Abstract: In this report, we show that deadlock avoidance for streaming computations with filtering can be performed efficiently for a large class of DAG topologies. We first give efficient algorithms for dummy interval computation in series-parallel DAGs, then generalize our results to a larger graph family, the CS4DAGs, in which every undirected cycle has exactly one source and one sink. Our results show that, for a large set of application topologies that are both intuitively useful and formalizable, the streaming model with filtering can be implemented safely with reasonable compilation overhead.

Type of Report: Other
Abstract—Parallel streaming computation has been studied extensively, and many languages, libraries, and systems have been designed to support this model of computation. While some streaming computations send data at a priori predictable rates on every channel between compute nodes, many natural applications lack this property. In particular, we consider acyclic streaming computations in which individual nodes can choose to filter, or discard, some of their inputs.

While streaming computation with filtering is an attractive model for many applications, if the channels between nodes have finite buffers, the computation can deadlock. One method of deadlock avoidance is to augment the data streams between nodes with occasional dummy messages; however, for general DAG topologies, no polynomial time algorithm is known to compute the intervals at which dummy messages must be sent to avoid deadlock.

In this report, we show that deadlock avoidance for streaming computations with filtering can be performed efficiently for a large class of DAG topologies. We first give efficient algorithms for dummy interval computation in series-parallel DAGs, then generalize our results to a larger graph family, the CS4 DAGs, in which every undirected cycle has exactly one source and one sink. Our results show that, for a large set of application topologies that are both intuitively useful and formalizable, the streaming model with filtering can be implemented safely with reasonable compilation overhead.

I. INTRODUCTION

Streaming is an effective paradigm for parallelizing complex computations on large datasets across multiple computing resources. Examples of application domains that use the streaming paradigm include media [1], signal processing [2], computational science [3], [4], data mining [5], and others [6]. Languages that explicit support streaming semantics include Brook [7], Cg [8], StreamC/KernelC [9], StreamIt [10], Streams-C [11], and X [12].

A streaming application is typically implemented as a network of compute nodes connected by unidirectional communication channels. Abstractly, the streaming application is a directed dataflow multigraph, with the node at the tail of each edge (channel) able to transmit data, in the form of one or more discrete messages, to the node at its head. In this report, we consider only directed acyclic multigraphs.

Many streaming languages and libraries support the synchronous dataflow (SDF) [13] model, where, for a given input message stream, the number of messages consumed and produced by each node on each channel incident on it is known at compile time. However, the assumptions of SDF are not an intuitively good fit for all streaming applications. In particular, the node’s decision on whether to send an output message in response to an input, and which subset of output channels to send messages on, may naturally be data-dependent. We say that nodes that can make such decisions at run-time exhibit filtering behavior.

Consider, for example, the simple split/join topology shown in Figure 1. In a streaming application, the split node A might analyze an input and decide to send it to some subset of its children for further processing. For example, an object recognition system might receive a video frame and, based on some initial segmentation and analysis in the split node, might forward that frame to one or more dedicated modules that recognize particular types of object. Each recognizer in turn might or might not trigger a “success” message to the join node D. Finally, any information collected at D might be sent downstream to be merged with other analyses that were performed in parallel on the same frame. Two applications of this type are considered in [14].

While filtering behavior can be simulated in an SDF framework by sending enough extra messages, such workarounds may be both unnatural for the application programmer and a waste of channel bandwidth. In particular, if many channels in the streaming application share the same physical resource (e.g., a common bus or network connection, or one CPU handling multiple message queues), the ability to filter might make the difference between an efficient application and one that suffers communication bottlenecks.

This work addresses the challenge of safely realizing streaming applications when nodes are permitted to filter. For most streaming languages, the programmer is allowed to assume infinite buffer capacity on channels that connect compute nodes. In practice, however, the compiler allocates a finite channel buffers. With finite buffers, a filtering application can deadlock, even if it has no directed cycles (this is not true for SDF DAGs). If a language provides infrastructural support for combining computational modules into a streaming topology with filtering, that language’s compiler and runtime should ensure that such deadlocks are avoided.

We formally modeled streaming computation DAGs with filtering and derived the precise conditions under which deadlock can occur in such DAGs [15]. We gave algorithms for

Fig. 1: A simple split/join streaming topology.
deadlock avoidance that work by sending occasional “dummy messages” between nodes. However, the intervals at which each node must emit these messages to avoid deadlock while minimizing dummy message traffic are in general challenging to compute. In particular, Our algorithms for computing dummy-message intervals run in worst-case time exponential in the size of the application’s topology, raising the question of whether a safe filtering paradigm can be implemented efficiently as part of compiling a streaming streaming application.

In this work, we show that for a large class of intuitive and useful DAG topologies, deadlock avoidance in the presence of filtering can be guaranteed efficiently. We first show that for series-parallel (SP) DAG topologies [16], which describe applications constructed by pipelining and parallel split-join, our dummy-message interval algorithms can be run in small polynomial time in the size of the DAG. We then extend these results to a larger family of topologies, the CS4 DAGs, that permit limited communication between parallel branches of a computation. We precisely characterize the structure of CS4 DAGs and use this structure to extend our efficient deadlock avoidance algorithms to them. The CS4 DAGs represent an abstraction that balances expressibility with efficiency of deadlock avoidance.

Related Work

SDF was generalized to Dynamic Data Flow (DDF) by Lee [17] and Buck [18]. In a DDF graph, firing of nodes can be determined through the use of of an explicit boolean-valued [17] or integer-valued [18] control input. In our model [15], this control information is encapsulated within the node and is therefore unavailable to the compiler and/or scheduler. Here, synchronization between multiple streams into each node is supported via the use of a non-negative sequence number associated with each data item.

StreamIt [10] is a streaming language and compilation toolkit, that supports slightly generalized SDF semantics. Applications of StreamIt are constructed from three topology primitives: pipeline, split-join, and feedback. While these three primitives generate hierarchical application topologies that facilitate compiler analysis, they limit the kinds of streaming topologies that StreamIt can support well [6]. In this report, we will discuss broader classes of DAG topologies than those that StreamIt supports. Moreover, unlike StreamIt’s split/join structures, which have special, language-defined semantics such as round-robin or broadcast, split and join nodes in this work can perform arbitrary computation and filtering just like any other node.

II. BACKGROUND

A. Model of Streaming Applications with Filtering

A streaming application in our model has a DAG topology of computation nodes connected by reliable, one-way communication channels, each of which has a finite channel buffer. Input messages to the application are assumed to arise at source nodes. Inputs are labeled with monotonically increasing sequence numbers, and all channels are assumed to deliver messages in FIFO order. A node accepts an input with sequence number $i$ when, for each of its input channels, the head of the channel buffer contains a message with sequence number $\geq i$. All messages with sequence number $= i$ are consumed together, and they may result in messages with sequence number $i$ being sent on any subset of the node’s output channels. If an input to a node does not result in an output on a given channel, we say that the node filters the input with respect to that channel.

We observed that in the presence of finite buffers between nodes, filtering behavior can lead to deadlock, as illustrated in Figure 2. If the buffer from $A$ to $C$ is empty because $A$ filters its output to $C$ and the buffers from $A$ to $B$ and $B$ to $C$ are full, the application is deadlocked. $A$ must wait for $B$ to consume an input before it can proceed; $B$ must wait for $C$ to consume an input; and $C$ must wait until it sees an input from $A$.

![Fig. 2: A deadlock condition in a streaming application.](image)

More generally, it can be proven that every potential deadlock in a DAG $G$ corresponds to some undirected cycle $C$ of $G$, which can be decomposed as a sequence of nodes with either two incoming or two outgoing directed paths on $C$. Roughly, a deadlock can occur whenever each of these nodes has a directed path with completely full buffers on one side, and an oppositely directed path with completely empty buffers (due to filtering) on the other side.

B. Deadlock Avoidance Through Dummy Messages

To avoid deadlock, We proposed two algorithms in which nodes periodically send dummy messages — content-free messages whose sequence number is that of some input that was filtered by the node. The idea of dummy messages originates in the parallel discrete-event simulation (PDES) literature [19], which used null messages for deadlock avoidance in conservative PDES algorithms.

In the first algorithm, the “Propagation Algorithm”, only nodes with two outgoing edges on some undirected cycle send dummy messages. A dummy is sent on a channel whenever its source has gone too long without sending a data message on the channel. Dummy messages may not themselves be filtered but must be propagated on all output channels of any node they reach. In the second algorithm, the “Non-Propagation Algorithm”, every node sends dummy messages, but the dummies need not be propagated past the channel on which they are emitted. Either algorithm can be implemented as a “wrapper” around each computational node in an application...
by the language compiler and runtime, with no participation by the application programmer.

To implement dummy message-based deadlock avoidance, the language compiler must use the finite lengths of each channel buffer to calculate the intervals at which every node must send dummy messages to ensure safety. The basic idea behind the calculating dummy intervals for the Propagation Algorithm is the following. Consider an edge \( e \) from node \( u \) to node \( v \). Let \( F \) be the set of edges starting at \( u \), and let \( C \) be the set of undirected simple cycles that contain both \( e \) and another edge from \( F - \{ e \} \). For a cycle \( C \in C \), let \( L(C, e) \) be the length of a shortest directed path on \( C \) (edge lengths are the buffer sizes on the edges) starting at \( u \) and not containing \( e \). The dummy interval \( [e] \) for \( e \) is then given by

\[
[e] = \min_{C \in C} L(C, e).
\]

The corresponding idea for the Non-Propagation Algorithm is the following. Consider an edge \( e \) from node \( u \) to node \( v \). Let \( C' \) be the set of undirected simple cycles containing \( e \), and for each cycle \( C \in C' \), let \( h(C, e) \) be as above. Let \( h(C, e) \) be the number of edges in a longest directed path (in terms of edge count) on \( C \) that contains \( e \). The dummy interval for \( e \) is then given by

\[
[e] = \min_{C \in C'} L(C, e)/h(C, e).
\]

**Proposition.** Let \( G \) be a node with at least two outgoing edges. Let \( W \) be the immediate postdominator of \( Z \). Then for any directed path \( P \) from \( Z \) to \( W \), \( Z \) dominates all nodes of \( P \) other than \( W \).

**Proof:** By induction on the structure of \( G \).

**Base:** in an SP-DAG with a single multi-edge, \( P \) is a single edge from \( Z \) to \( W \). \( Z \) trivially dominates itself.

**Ind.:** Otherwise, \( G \) is either \( Sc(H_1, H_2) \) or \( Pc(H_1, H_2) \) for SP-DAGs \( H_1, H_2 \). If \( Z \) is the source of \( G \), then \( Z \) trivially dominates all of \( G \), since SP-DAGs have a single source. \( Z \) can not be the sink of \( G \) since the sink has no outgoing edges. Now \( Z \) lies either in \( H_1 - H_2 \) or in \( H_2 - H_1 \), or \( G = Sc(H_1, H_2) \) and \( Z \) is the sink of \( H_1 \) and the source of \( H_2 \). If \( Z \) is in \( H_1 - H_2 \), then \( H_1 \)'s sink always postdominates \( Z \), so \( W \), the immediate postdominator of \( Z \), is a node in \( H_1 \). Applying the IH to subgraph \( H_1 \), the Lemma holds for \( Z \) and \( W \). Analogous reasoning holds if \( Z \) is in \( H_2 - H_1 \). Finally, if...
Z is the source of $H_2$ and the sink of $H_1$, then $W$ is in $H_2$ and $Z$ dominates all of $H_2$.

Proof for Lemma III.4.

**Proof:** By induction on the structure of $G$.

**Base:** Trivially true for a single multi-edge.

**Ind.:** If $G = Sc(H_1, H_2)$, then the property holds for $H_1$ and $H_2$, and their serial composition creates no new cycles. Hence the property holds for every cycle of $G$.

If $G = Pc(H_1, H_2)$, then every new cycle created by their parallel composition connects the common source $X$ of $G$ to its common sink $Y$ by directed paths passing through $H_1$ and $H_2$, respectively. All such cycles therefore have one source $X$ and one sink $Y$.

**Lemma III.2.** Let $G = Pc(H_1, H_2)$ be an SP-DAG, where $X$ is its source and $Y$ is its sink. Let $Z$ be a node of $H_1 - \{X,Y\}$ that has at least two outgoing edges $e$ and $e'$ in $G$. Let $C$ be an undirected simple cycle that contains both $e$ and $e'$. Then $C$ contains no edge edge $e'' \in H_2$.

**Proof:** Suppose not. WLOG, let the counterexample simple cycle $C$ leave $Z$ via edge $e = Z \to U$ and return via edge $e' = Z \to V$. Since $C$ passes through an edge in $H_2$, it must also pass through both $X$ and $Y$, since those are the only two nodes that connect $H_1$ and $H_2$. So there must be two vertex-disjoint undirected paths in $H_1$: $P_1$ goes from $Z$ to $U$ to $Y$, and $P_2$ (entirely in $H_1$) goes from $Z$ to $V$ to $X$.

Let $W$ be the immediate postdominator of $Z$, which lies in $H_1$. We claim that both paths $P_1$ and $P_2$ must pass through $W$.

Suppose path $P_1$ does not pass through $W$. Now $U$ is a predecessor of $W$, while $Y$ is not, so there is some first edge in $P_1$ that connects a predecessor $A$ of $W$ to a non-predecessor $B$. We have two cases.

1) First, say this edge is oriented $A \to B$, then there is a directed path from $Z$ to $A$ to $B$ to $Y$ that bypasses $W$, which contradicts $W$’s postdominance of $Z$.

2) If the edge is oriented $B \to A$, then $B$ is not a successor of $W$, since $G$ is acyclic. There is then a directed path from $X$ to $B$ to $A$ that bypasses $Z$, which contracts $Z$’s domination of $A$ by Lemma III.1.

Conclude that $P_1$ must indeed pass through $W$.

Suppose $P_2$ doesn’t pass through $W$. Now $V$ is a successor of $Z$, while $X$ is not; hence, there is some first edge on path $P_2$ that connects a successor $A$ of $Z$ to a non-successor $B$. This edge must be oriented $B \to A$, else $B$ would be a successor of $Z$.

Now $A$ cannot be a predecessor of $W$; otherwise, there would be a directed path from $X$ to $B$ to $A$ that bypasses $Z$, contradicting $Z$’s dominance of $A$ by Lemma III.1. Hence, $A$ is a successor of $W$. The subpath of $P_2$ from $V$ to $A$ therefore contains some first edge connecting a predecessor $C$ of $W$ to a successor $D$ of $W$. This edge must be oriented $C \to D$, since $G$ is acyclic. But then there is a directed path from $Z$ to $C$ to $D$ to $Y$ that bypasses $W$, which contradicts $W$’s postdominance of $Z$. Conclude that $P_2$ must indeed pass through $W$.

Since $P_1$ and $P_2$ both contain $W$, they are not vertex disjoint, leading us to a contradiction.

**Corollary III.3.** For an SP-DAG $G = Pc(H_1, H_2)$, any undirected simple cycle $C$ in $G$ that has edges in both $H_1$ and $H_2$ consists of a pair of directed paths $P_1$ through $H_1$ and $P_2$ through $H_2$ that connect the source $X$ of $G$ to its sink $Y$.

**Proof:** We know from Lemma III.2 that undirected simple cycles in $G$ that traverse edges of both $H_1$ and $H_2$ do not pass through two outgoing edges of any node other than $X$. Moreover, each such cycle passes through two incoming edges of node $Y$, since $Y$ does not have any outgoing edges.

Let $P_1$ be the directed path on $C$ that exits $X$ in (WLOG) $H_1$. If this path were to terminate at some node $Z$ prior to $Y$, then the portion of cycle following $P_1$ would traverse two adjacent incoming edges of $Z$. But if the cycle leaves $Z$ via an edge that points into $Z$ and eventually reaches $Y$ via an edge that points into $Y$, it must at some point “change direction” by passing through two outgoing edges of a node $Q$ other than $X$, which is impossible by Lemma III.2.

Conclude that $C$ must be fully directed from $X$ to $Y$ in both components.

**Lemma III.4.** Each undirected simple cycle in an SP-DAG $G$ has a single source and a single sink.

**IV. EFFICIENT DEADLOCK AVOIDANCE FOR SP-DAGS**

The structured nature of series-parallel graphs is known to permit efficient algorithms for a variety of combinatorial problems, including some that are NP-hard on general graphs [20]. Similarly, we show in this section that the nice cycle structure of SP-DAGs allows us to efficiently prevent deadlock. In particular, we prove that we can compute the dummy intervals for all edges for the Propagation Algorithm in $O(|G|)$ time and for the Non-Propagation algorithm in $O(|G|^2)$ time.

**A. Computing dummy intervals for the Propagation Algorithm**

Dummy interval computation consists of the following steps:

1) We first recursively decompose $G$ according to the construction rules for SP-DAGs, using e.g. the linear-time recognition algorithm of Valdes, Tarjan, and Lawler [16]. The decomposition results in a tree $T$ whose leaves are single (multi-)edge graphs and whose internal nodes are labeled with the composition operators $Sc$ or $Pc$, such that applying the composition operations in post-order results in graph $G$. The size of this tree is $O(|G|)$.

2) For every component $H$ of $G$, we compute $L(H)$, which is the length of a shortest directed path (with buffer lengths as edge weights) from the source of $H$ to its sink. This calculation can be done bottom-up on the tree $T$ in $O(|G|)$ time.

3) We then compute the dummy intervals for each edge. Naively, we can update intervals once for each edge for each component of $T$, for a total time $O(|G|^2)$ (since SP-DAGs are planar and so have $O(|G|)$ edges). However,
we also give a more sophisticated algorithm that can compute all dummy intervals in $O(|G|)$ time with a top-down algorithm.

For step 2 of the above procedure, the following algorithm allows us to use the component tree $T$ to compute shortest paths from source to sink for each component of $G$ in $O(|G|)$ time. For a single multi-edge $X \rightarrow Y$, we can compute a shortest path from $X$ to $Y$ in time proportional to the number of edges. Given shortest path lengths $L(H_1)$ and $L(H_2)$ from source to sink in SP-DAGs $H_1$, $H_2$, we can compute this length for their composition $H$ in constant time as follows:

- If $H = Sc(H_1, H_2)$, $L(H) = L(H_1) + L(H_2)$.
- If $H = Pc(H_1, H_2)$, $L(H) = \min(L(H_1), L(H_2))$.

For step 3 above, we can naively compute all dummy intervals in $O(|G|^2)$ time during a post-order traversal of $T$ as follows. Let $H$ be a component of $G$.

**Case 1:** Say $H$ is a leaf of $T$ corresponding to a multi-edge $X \rightarrow Y$. The dummy interval $[e]$ for edge $e$ is the minimum buffer size over all edges other than $e$ between $X$ and $Y$. If $X \rightarrow Y$ is only a single edge, then $[e] = \infty$.

**Case 2:** Say $H = Sc(H_1, H_2)$. Since $H_1$ and $H_2$ are joined by a single articulation point, their composition creates no new simple cycles. The dummy intervals for edges in $H_1$ and $H_2$ do not change.

**Case 3:** Say $H = Pc(H_1, H_2)$, and $X$ is $H$’s source. For each node $Z \in H - \{X\}$ with two outgoing edges $e$ and $e'$, Lemma III.2 proves that the parallel composition introduces no new simple cycle that leaves $Z$ via $e$ and returns via $e'$. Hence, the dummy intervals for these nodes’ outgoing edges do not change. For the source $X$ itself, the composition creates undirected cycles consisting of two directed paths from $X$ to $Y$, as shown in Corollary III.3. Each such cycle leaves $X$ via some $e \in H_1$ and returns via some $e' \in H_2$. Recall that we precomputed $L(H_1)$ and $L(H_2)$ as the total buffer lengths on some shortest (by total buffer length) directed path from $X$ to $Y$ in $H_1$ and $H_2$, respectively. Now each $e$ out of $X$ in $H_1$ already has some dummy interval $[e]$. Then we update $[e]$ as follows. For each edge $e$ out of $X$ in $H_1$:

$$[e] \leftarrow \min([e], L(H_2)).$$

Similarly, for each edge $e'$ out of $X$ in $H_2$, we set

$$[e'] \leftarrow \min([e'], L(H_1)).$$

By definition of $L$, we can always find a new cycle through $e/e'$ that realizes the claimed shortest dummy interval.

Naïvely, we must update dummy intervals for every edge in a component when that component is processed, which could entail $O(|G|^2)$ edge updates over the entire tree. However, Algorithm I computes dummy intervals for all edges of $G$ in top-down manner in time $O(|G|)$. We initially call SETIVALS$(G, \infty)$ on the full graph $G$.

**Definition.** A cycle in graph $G$ is external to a subgraph $H$ if it passes through some edge of $G - H$. If the cycle does not pass through any edge in $G - H$, it is internal to $H$.

**Algorithm 1: SETIVALS(G,V)

```plaintext
/* Set dummy interval on SP-DAGs for Prop. Algo. */
/* [e]: dummy interval for e; |e|: length of e */
if G is a single multi-edge X \rightarrow Y then
  foreach edge e in the multi-edge do
    [e] \leftarrow \min(V, \min_{e' \in \{X \rightarrow Y - e\}} |e'|)
else if G = Pc(H_1, H_2) then
  /* parallel composition */
  SETIVALS(H_1, min(V, L(H_2)))
  SETIVALS(H_2, min(V, L(H_1)))
else /* series composition */
  SETIVALS(H_1, V)
  SETIVALS(H_2, \infty)
```

**Claim IV.1.** Let $H$ be a component of $G$, and let $X$ be its source. When we call SETIVALS$(H, V)$, $V$ is the smallest dummy interval for edges out of $X$ that is required by any cycle that passes through $X$ but is external to $H$.

**Proof:** By induction from larger to smaller components.

**Base:** In the initial call to SETIVALS, $V = \infty$, which is appropriate because there is no cycle passing through the source of $G$ that is not confined to $G$.

**Ind.:** Suppose $V$ is set as claimed on entry to SETIVALS for component $H$. We will show that the claim holds for the recursive calls that result if that $H = Pc(H_1, H_2)$ or $H = Sc(H_1, H_2)$.

Say $H = Pc(H_1, H_2)$. Let $e$ be an edge out of $X$ in $H_1$. $L(H_2)$ represents the minimum dummy interval required for edge $e$ due to any cycle that passes through $X$, is external to $H_1$, but is internal to $H$. By our IH, $V$ is the minimum interval required for $e$ due to any cycle that passes through $X$ and is external to $H$. Hence, the code correctly updates $V$ for $H_1$. Analogous reasoning holds for $H_2$.

If $H = Sc(H_1, H_2)$, then $H_1$ and $H_2$ are connected by a single vertex which is the sink of $H_1$ and the source of $H_2$. Hence, there is no simple cycle that traverses both $H_1$ and $H_2$ and is internal to $H$. $V$ therefore remains the correct value to pass for $H_1$. For $H_2$, we know by Lemma III.2 that no cycle considered thus far enters and leaves $H_2$’s source through outgoing edges, so there is not yet any constraint on the smallest dummy interval for these edges. Hence, we set correctly set $V = \infty$.

Conclude in all cases that $V$ is correctly updated for the recursive calls.

**Corollary IV.2.** SETIVALS correctly sets $[e]$ for all edges of $G$ in time $O(|G|)$.

**Proof:** The dummy intervals for edges are set only in the base case of SETIVALS. By our Claim above, when we call SETIVALS in this base case, $V$ is the smallest dummy interval required for any edge in the given multi-edge, other than for trivial cycles involving two edges of the same multi-edge. Hence, the base case correctly sets $[e]$ for all edges in
Conclude that the entire algorithm is \(O(|G|)\), as desired.

B. Computing dummy intervals for the Non-Propagation Algorithm

We now show how to efficiently calculate dummy intervals for the Non-Propagation Algorithm. The approach is broadly similar to that for the Propagation Algorithm, except that the interval \([e]\) now minimizes a ratio between the length of a component-dependent shortest path and the number of hops in an edge-dependent longest path.

1) Decompose the graph into a tree of components.
2) Compute \(L(H)\) for each component \(H\).
3) Compute \(h(H)\) for each component \(H\), where \(h(H)\) is the longest path (in terms of the number of hops) from the source of \(H\) to its sink.
   - For a single multi-edge, \(h(H) = 1\).
   - If \(H = Sc(H_1, H_2)\), \(h(H) = h(H_1) + h(H_2)\).
   - If \(H = Pc(H_1, H_2)\), \(h(H) = \max(h(H_1), h(H_2))\).
4) Compute \(h(H, e)\) for each edge \(e \in H\), where \(h(H)\) is the longest path (in terms of the number of hops) from the source of \(H\) to its sink that passes through \(e\). For a single multi-edge, \(h(H, e) = 1\). For a series composition, for all \(e \in H_1\), \(h(H, e) = h(H_1, e) + h(H_2)\). Similarly for \(e \in H_2\), \(h(H, e) = h(H_2, e) + h(H_1)\). For parallel composition, if \(e \in H_2\), \(h(H, e) = h(H_1, e)\). Similarly for \(e \in H_2\). All these computations can be done in \(O(|G|^2)\) time.
5) Compute the dummy interval \([e]\) for each edge \(e\) in a bottom-up fashion.

The first four steps in the above procedure are straightforward. For the fifth step, we visit the components of \(T\) in post-order. When considering component \(H\), we update \([e]\) for all the edges in \(H\) considering only cycles internal to \(H\).

Case 1: If \(H\) is a multi-edge from \(X \rightarrow Y\), let \(e\) be an edge from \(X\) to \(Y\). If we consider only cycles internal to \(H\), \(L(H, e)\) is the minimum buffer size over all edges other than \(e\) between \(X\) and \(Y\), and \(h(H, e) = 1\). Therefore, the calculation in this case is identical to the calculation for the Propagation Algorithm.

Case 2: If \(H = Sc(H_1, H_2)\), serial composition introduces no new simple cycles through \(e\), so \([e]\) is unchanged.

Case 3: If \(H = Pc(H_1, H_2)\), suppose WLOG that \(e\) is in \(H_1\). Let \(X\) be the source of \(H\), and let \(Y\) be its sink. Every new cycle created by the parallel composition consists of two confluent paths from \(X\) to \(Y\), one in each of \(H_1\) and \(H_2\). Let \(C\) be the newly created cycle that traverses a longest (in hop count) directed path in \(H_1\) that includes \(e\) and returns via a shortest (in buffer length) path in \(H_2\). Then the ratio \(L(C, e)/h(C, e)\) for \(C\) is minimum among all new cycles created by the composition. Since, \(L(C, e) = L(H_2)\) and \(h(C, e) = h(H_1, e)\), we have \([e] = \min([e], L(H_2)/h(H_1, e))\). The symmetric computation applies if \(e\) is in \(H_2\).

Each case above takes constant time per edge in the component \(H\), or \(O(|G|)\) time per component. Conclude that the entire tree traversal is \(O(|G|^2)\).

V. CS4 DAGs: A larger set of simple streaming topologies

We have shown how to efficiently prevent deadlock in SP-DAGs – a large, practically useful class of DAG topologies that can be constructed with simple composition operations. A natural question at this point is, do there exist “natural” topologies that are not SP-DAGs? Might these topologies also have efficient algorithms for deadlock avoidance?

Figure 4 shows two simple two-terminal DAGs that are not SP-DAGs. The topology on the left augments a trivial split/join with a one-way communication channel linking its two sides; it is perhaps the simplest DAG that is not series-parallel. The topology on the right adds slightly more complexity, creating a “butterfly” structure like that commonly used to decompose large FFT computations. A key feature distinguishing the two graphs is that, in the left-hand example, every undirected simple cycle has only one source and one sink. This property is true for SP-DAGs, and we exploited it implicitly in the algorithms of the previous section. On the other hand, the butterfly graph contains a cycle \(a-c-b-d\) with two sources and two sinks.

In this section, we characterize the set of all DAGs whose undirected cycles each contain one source and one sink. The next section shows that all such DAGs are amenable to efficient deadlock avoidance using generalizations of our algorithms from Section IV. In contrast, we can provide no such guarantee for graphs like the butterfly that have cycles with multiple sources and sinks. For such graphs, the programmer (or possibly the compiler) would need to construct an alternative topology to obtain efficient deadlock avoidance using our methods.

Definition. Let \(G\) be a DAG with a single source and sink. We say that \(G\) is “CS4” if every undirected simple cycle in \(G\) has a single source and a single sink.

Lemma V.1. \(G\) is CS4 only if no subgraph of \(G\) is homeomorphic to \(K_4\), the complete graph on 4 vertices.
Proof: Suppose $G$ has a subgraph $H$ homeomorphic to $K_4$. $H$ has 4 “corner” vertices and 6 connections (which may in general be paths rather than single edges) connecting them in the pattern of $K_4$. There are therefore 12 incidences of connections on corner vertices in $H$. WLOG, suppose that at least 6 of these are incoming. Now we have two cases.

1) Two vertices $X$ and $Y$ of $H$ have exactly two incoming edges apiece.
2) One vertex has 3 incoming edges.

Consider case 1. If the (unique) shared connection between $X$ and $Y$ is oriented identically w/r to $X$ and $Y$ (either into both or out of both), then it is possible to find a cycle through $X$ and $Y$ with two sinks. Now consider the case when the connection $X - Y$ is directed out of one vertex and into the other. Suppose WLOG that connection $x - y$ is directed out of $X$ and into $Y$. Let $W$ and $Z$ be the other two corner vertices of $H$.

Exactly one of the connections $Y - W$ and $Y - Z$ must be directed out of $Y$. Suppose WLOG that $Y - Z$ is directed out of $Y$. Because each of $X$ and $Y$ have exactly two incoming edges, we know the following: (1) $X - Z$ must be directed into $X$; (2) $W - X$ must be directed into $X$; (3) $W - Y$ must be directed into $Y$. Now $Y - Z$ must be directed into $Z$; otherwise, there must be a sink on this connection, and the cycle $X W Y Z$ would contain two sinks. It follows that $X - Z$ is directed out of $Z$; otherwise, $X$ and $Z$ would constitute the forbidden case (1).

Now we established above that $Y - Z$ may not contain a sink. Similarly, $X - Z$ may not contain a sink because of cycle $X W Z$, and $X - Y$ may not contain a sink because of cycle $X W Y$. Hence, cycle $X Y Z$ must be a directed cycle, which is forbidden because $G$ is a DAG.

Consider case 2 above, where one corner vertex $v$ of $H$ has three incoming edges. Then no other corner vertex of $H$ can have two incoming edges without creating a cycle with two sinks. Since $H$ has at least six incoming edges on its corner vertices, it follows that the other three corner vertices of $H$ each have exactly one incoming, and hence two outgoing, edges. Repeat the argument of Case (1) for any two of these vertices, swapping “in” and “out”.

Conclude that there is no way to direct the edges of $H$ so as to ensure that all its cycles have one source and one sink.

**Corollary V.2.** Every CS4 graph is planar.

**Proof:** If $G$ contains no subgraph homeomorphic to $K_4$, then it contains no subgraph homeomorphic to either $K_5$ or $K_{3,3}$, both of which contain subgraphs homeomorphic to $K_4$. By Kuratowski’s Theorem, $G$ must be planar.

Now absence of $K_4$ is a characteristic property of undirected series-parallel graphs [21]. Hence, we may expect that CS4 DAGs have an undirected series-parallel structure. However, this does not imply that a CS4 DAG is an SP-DAG; our simple four-node graph above provides a counterexample. Fortunately, as we now show, it turns out that just a small amount of extra complexity is needed to capture all CS4 DAGs.

**Definition.** A 2-path cycle is a DAG consisting of a single source $X$, a single sink $Y$, and two directed paths connecting $X$ to $Y$ that are disjoint except at their endpoints.

**Definition.** Let $C$ be a cycle. A chord graph $H$ is a DAG with a single source and sink that connects two vertices of $C$, and $H$’s source and sink lie on $C$.

**Definition.** Let $C$ be a 2-path cycle with paths $P_1$ and $P_2$. A cross-link is a chord graph that connects a vertex of $P_1$ to a vertex of $P_2$, where neither endpoint of the connection is $C$’s source or sink.

**Definition.** An SP-ladder $G$ is a DAG consisting of a 2-path cycle with paths $P_1$ and $P_2$, called the outer cycle of $G$, and one or more chord graphs $H_1 \ldots H_k$, such that:

- Each $H_i$ is an SP-DAG;
- At least one $H_i$ is a cross-link;
- If $G$ contains two chord graphs with endpoints $(u_1, v_1)$ and $(u_2, v_2)$, then these chord graphs do not cross; that is, in tracing the outer cycle around $G$, we never encounter both $u_2$ and $v_2$ between $u_1$ and $v_1$.

Intuitively, we call $G$ an SP-ladder because it can be viewed as a 2-path cycle “decorated” with non-cross-link chord graphs, plus one or more cross-links connecting the paths, none of which cross each other. The cross-links are similar to the rungs of a ladder. Examples of simple and complex SP-ladders are given in Figure 5.

**Definition.** Say that a cycle $C$ of SP-ladder $G$ traverses a chord graph $H$ if $C$ passes through a node of $H$ other than its source or sink but is not confined to $H$.

**Fact V.3.** If an undirected simple cycle $C$ in $G$ traverses a chord graph $H$, then $C$ contains a directed path in $H$ from its source $u$ to its sink $v$.

**Proof:** $C$ reaches an internal vertex of $H$ from outside, so it must consist of a simple path $P$ in $H$ that connects $u$ to $v$, plus a path to return from $v$ to $u$ outside $H$. We claim that path $P$ is directed. Suppose not; $P$ enters and leaves $H$ through edges directed out of its source and into its sink, so $P$ must contain an internal source at some node $Z$. But Lemma III.2 showed that there is no simple path connecting the source and sink of $H$ that contains an internal source.

**Lemma V.4.** Suppose that $C$ traverses $k \geq 0$ cross-links of $G$. Then there is a cycle $C'$ in $G$ with at least as many sources/sinks as $C$ that does not traverse any cross-link of $G$.

**Proof:** By induction on $k$.

**Base:** Trivially true if $k = 0$; set $C' = C$.

**Ind.:** Suppose that $C$ traverses $k$ cross-links of $G$. Order these links as $H_1 \ldots H_k$ in topologically increasing order of their endpoints (which is possible, because they cannot cross). Let $u_i < v_i$ be the endpoints of $H_i$ in $G$.
We claim that either $C$ does not pass through any strict predecessor of $u_1$ or $v_1$, or that it does not pass through any strict successor of $u_k$ or $v_k$. Since $C$ traverses $H$, it contains a directed path from $u_1$ to $v_1$. Starting from $v_1$, $C$ must return by some undirected path $P$ to $u_1$. Now if the first edge on this path touches a predecessor of $v_1$, then $C$ must return to $u_1$ without touching any successor of $u_1$ or $v_1$; indeed, to reach $w$ without passing through $u_1$ or $v_1$, the path would have to traverse a chord graph that crosses $H$, which cannot exist. If, on the other hand, $P$'s first edge touches a successor of $v_1$, then $C$ must return to $u_1$ without touching any predecessor of $u_1$ or $v_1$, for the same reason.

Suppose that $C$ does not touch a predecessor of $u_1$ or $v_1$. Construct $C'$ from $C$ by removing the path through $H$ and replacing it with the path on $G$'s outer cycle that connects $u_1$ and $v_1$, passing through $G$'s source $X$. $C'$ does not contain the source that lies at endpoint $u_1$ of $H$, but it does contain a new source at $X$. Removing $H$ cannot eliminate any other source or sink of $C$, so $C'$ has as many sources/sinks as $C$.

If instead $C$ does not touch a successor of $u_k$ or $v_k$, construct $C''$ from $C$ by removing the path through $H$ and replacing it with the path on $G$'s outer cycle that directly connects $u_k$ and $v_k$, passing through $G$'s sink $Y$. $C''$ does not contain the sink that lies at endpoint $v_k$ of $H$, but it does contain a new sink at $Y$. Removing $H$ cannot eliminate any other source or sink of $C$, so $C''$ has as many sources/sinks as $C$.

By the IH, there is a cycle $C''$ in $G$ with at least as many sources/sinks as $C'$ that does not pass through any cross-link of $G$.

**Corollary V.5.** Every SP-ladder is CS4.

**Proof:** Let $C$ be any cycle in an SP-ladder $G$. If $C$ traverses $k > 0$ cross-links of $G$, Lemma V.4 guarantees that there is a cycle $C''$ that does not traverse any cross-links of $G$ with at least as many sources/sinks as $C$.

Now either $C'$ is confined to some chord graph $H$ of $G$, or $C''$ lies in the graph $G'$ obtained by removing all cross-links from $G$. $H$ and $G'$ are both SP-DAGs, which are CS4 by Lemma III.4. Hence, $C''$ has only one source and one sink.

Conclude that $C$ has only one source and one sink, and so $G$ is CS4.

**Lemma V.6.** Let $G$ be a DAG with a single source and sink that is CS4. Then $G$ is a serial composition of one or more graphs $G_1\ldots G_k$, s.t. each $G_i$ is either an SP-DAG or an SP-ladder.

**Proof:** Divide $G$ into subgraphs $G_1\ldots G_k$ at its articulation points, so that $G$ is the serial composition of $G_1\ldots G_k$. If every $G_i$ is an SP-DAG, we are done. Otherwise, let $G^*$ be a component of $G$ that is not an SP-DAG. Now $G^*$ has no internal articulation points, so it is composed of a 2-path outer cycle cut by one or more chord graphs.

Let $H_1$, $H_2$ be two chord graphs in $G^*$, with endpoints $u_1/v_1$ and $u_2/v_2$. If these subgraphs cross, then there exist paths $P_1$ connecting $u_1$ and $v_1$ in $H_1$ and $P_2$ connecting $u_2$ and $v_2$ in $H_2$. Moreover, $G^*$'s outer cycle contains $u_1$, $v_1$, $u_2$, and $v_2$ in some alternating order. Hence, the union of $P_1$, $P_2$, and this cycle is homeomorphic to $K_4$, and so $G^*$ (and hence $G$) cannot be CS4. Conclude that no two chord graphs of $G^*$ cross.

Now suppose that some chord graph $H$ is not an SP-DAG. Let $H^*$ be a smallest subgraph of $H$ that is not an SP-DAG. $H^*$ cannot be a serial composition of multiple subgraphs, so it is a 2-path outer cycle with one or more chord graphs, all of which are SP-DAGs. If $H^*$ had no cross-link, we could decompose it as an SP-DAG via repeated parallel compositions to extract all of its chord graphs. Hence, some chord graph $J$ of $H^*$ is a cross-link.

Let $u$, $v$ be the endpoints of $J$, and let $x$, $y$ be its source and sink. The outer cycle of $H^*$ connects these vertices in the order $x - u - y - v$. Moreover, there is a path from $u$ to $v$ bypassing $X$ and $Y$ (through the cross-link) and a path from $X$ to $Y$ bypassing $u$ and $v$ (from $X$ outwards to the source of $H$, then via the outer cycle of $G^*$ to the sink of $H$, and finally inwards to $y$). The union of these two paths and the outer cycle of $H^*$ is therefore homeomorphic to $K_4$, and so $H^*$ (and hence $G$) cannot be CS4. Conclude that $H^*$, and therefore $H$, cannot exist, so every chord graph of $G^*$ is indeed an SP-DAG.

Finally, if no chord graph of $G^*$ is a cross-link, $G^*$ can be decomposed via repeated parallel compositions to expose all its chord graphs and so is an SP-DAG. Otherwise, it is an SP-ladder. Conclude that every component of $G$ is either an SP-DAG or an SP-ladder.

**Theorem V.7.** The set of single-source, single-sink CS4 DAGs is exactly the family of graphs of which each one is a serial composition of one or more graphs $G_1\ldots G_k$, s.t. each $G_i$ is either an SP-DAG or an SP-ladder.

**Proof:** Lemma V.6 shows that every single-source, single-sink CS4 DAG is in the claimed family. Conversely, Lemma V.1 and Corollary V.5 show that SP-DAGs and SP-ladders respectively are CS4. Serial composition of such graphs cannot introduce new cycles, so all such compositions remain CS4.

**VI. EFFICIENT DEADLOCK AVOIDANCE FOR CS4 DAGS**

We now present algorithms to compute optimal dummy intervals for deadlock avoidance on CS4 graphs. Since a CS4 graph is serial composition of SP-DAGs and SP-ladders, edges on different SP-DAGs and SP-ladders cannot be on the same simple cycle. Hence, we can first decompose a CS4 graph into SP-DAGs and SP-ladders, then compute dummy intervals on these subgraphs separately. We have already described algorithms for SP-DAGs, so here we focus on SP-ladders.

An SP-ladder can be decomposed into its constituent SP-DAGs as shown in Figure 5, where each edge represents an SP-DAG directed the same way as the edge. This simplified representation of an SP-ladder has two paths from the source $X$ to the sink $Y$. For convenience, we assume the two paths go from top to the bottom and distinguish them as the “left
path” and the “right path”. We mark the vertices that connect these paths to cross-links from top to bottom, with the vertices on the left labeled $u_0, u_1, u_2, \ldots, u_{k+1}$ and the vertices on the right path from to bottom labeled $v_0, v_1, v_2, \ldots, v_{k+1}$. The source $X = u_0 = v_0$ and the sink $Y = u_{k+1} = v_{k+1}$. This graph has $k$ cross-links, which are numbered from top to bottom as $K_1$ through $K_k$, and the SP-DAGs on the outer cycle are numbered $S_0$ through $S_k$ on the left and $D_0$ through $D_k$ on the right. Note that in some cases, $u_i = u_{i+1}$ and then $S_k$ is a graph with a single node. Figure 6 illustrates the general decomposition and this special case.

**Fact VI.2.** Any external cycle with source $X = u_0 = v_0$ has a path through $S_i$ and another path through $D_0$. In addition, any external cycle with internal source $u_i$ ($i \neq 0$) has one path going through $S_i$ and another path going through $K_i$. Similarly for internal source $v_i$.

**Lemma VI.3.** Consider any external cycle $C$ with source $u_i$. The sink of this cycle has 3 possibilities: (1) $u_j$, where $j > i$ and $K_j$ goes from right to left, (2) $v_j$, where $j > i$ and $K_j$ goes from left to right, or (3) $Y$, the sink of the ladder.

We call the sinks defined in Lemma VI.3 the **potential sinks** of $u_i$. We can similarly define potential sinks for an internal source $v_i$.

### A. Computing dummy intervals for Propagation Algorithm

The overall algorithm for finding dummy intervals for the propagating algorithm for an SP-ladder is given below; it runs in time $O(|G|)$, just as for SP-DAGs.

1) Decompose the SP-ladder into the component SP-DAGs, identifying the $u_i$’s, $v_i$’s, $S_i$’s, $D_i$’s and $K_i$’s. In addition, we mark each edge as either belonging to a cross-link or not. This can be done in $O(|G|)$ time.

2) Compute dummy intervals for all edges due to cycles internal to each component SP-DAG, using the algorithm of Section IV.

3) For all $H \in \bigcup_{0 \leq i \leq k} S_i \cup D_i \cup K_i$, compute $L(H)$, which is the length of the shortest path from $H$’s source to its sink (in terms of buffer sizes). Again, this is done as shown in Section IV.

4) Starting at the bottom of the SP-ladder, for each $u_i$, we compute $L_s(u_i)$, which is defined as the shortest directed path starting at $u_i$, going through $S_i$, and ending at a potential sink of $u_i$. Similarly define $L_k(u_i)$ as the shortest directed path starting at $u_i$, going through $K_i$, and ending at one of the potential sinks of $u_i$. If $u_i$ is not the source of $K_i$, then we just set $L_k(u_i) = 0$. We define $L_d(v_i)$ and $L_k(v_i)$ in a similar manner, and compute those too.

5) Using these $L$ values, we can update the dummy intervals for all edges that start at internal sources and at source $X$. No other dummy intervals change.

For step 1, we can decompose an SP-ladder into its constituent SP-DAGs in $O(|G|)$ time as follows: Identify an outer cycle $C$ for $G$ with left and right sides, using DFS in linear time. For each vertex $u$ on the left side of $C$, determine (via DFS) whether any directed path leaving $u$ encounters the right side of $C$ at some vertex $v$ before it encounters the left side again. If so, the nodes and edges on all such paths from $u$ to $v$ form a cross link. Repeat for the right side of $C$ to identify cross-links directed from right to left. Now that we have identified all $u_i$’s and $v_i$’s, we can easily compute $S_i$’s, $D_i$’s and $K_i$’s.

---

**Definition.** We say that an undirected simple cycle is **external** if it traverses at least two of the constituent SP-DAGs.

**Definition.** A node $s$ is an **internal source** if there exists an external cycle $C$ that has $s$ as its source, and $s \neq X$.

**Fact VI.1.** An internal source is either (1) $u_i$ if $K_i$ goes from left to right, or (2) $v_i$ if $K_i$ goes from right to left.
For step 4 above, we can compute \( L_s(u_i) \) and \( L_k(u_i) \) starting at the bottom of the SP-ladder as follows:

\[
\begin{align*}
L_k(u_{k+1}) &= 0 \\
L_s(u_{k+1}) &= 0 \\
L_s(u_i) &= L(S_i) + \min \left\{ \begin{array}{ll}
L(K_{i+1}) + L_s(u_{i+1}) & \text{if } u_{i+1} \text{ is } K_{i+1}'s \text{ source} \\
0 & \text{otherwise}
\end{array} \right\
\end{align*}
\]

\[
L(k(u_i)) = \begin{cases} 
L(K_i) + L_d(V_i) & \text{if } u_i \text{ is } K_i's \text{ source} \\
0 & \text{otherwise}
\end{cases}
\]

The calculations for \( v_i \) are analogous. Now for the propagation algorithm, suppose \( u_i \) is the source of a cross-link \( K_i \) directed left-to-right. Then for each edge \( e \) out of \( u_i \), if \( e \) lies in \( K_i \), then \( [e] = \min([e], L_s(u_i)) \). Recall that \( L_s(u_i) \) is length of a shortest path, say \( p \), that starts at \( u_i \), goes through \( S_i \), and ends at some potential source, say \( t \) of \( u_i \). This dummy interval update covers all cycles that go to \( t \) via \( p \) and then returns to \( u_i \) via \( K_i \). Similarly \( [e] = \min([e], L_k(u_i)) \) if \( e \) lies in \( S_i \). We can similarly update all edges out of \( v_i \). To update each edge \( e \) out of \( X \), \( [e] = \min([e], L_v(t)) \) if \( e \) lies in \( S_0 \), and \( [e] = \min([e], L_v(t)) \) if \( e \) lies in \( D_0 \).

B. Computing dummy intervals for Non-Propagation Algorithm

Computing the dummy intervals for the Non-Propagation Algorithm takes longer. Here we give an \( O((|G|)^3) \) algorithm. Again, we decompose into constituent SP-DAGs. As in the Non-Propagation Algorithm for SP-DAGs, for each constituent SP-DAG \( H \), we precompute \( h(H) \) as the length of the longest path (in terms of the number of hops) from \( H \)'s source to its sink. In addition, for each edge \( e \) in \( H \), compute \( h(H, e) \) as the longest path from \( H \)'s source to its sink that passes through \( e \). In addition, we compute the initial estimate of the dummy intervals considering only the cycles internal to the constituent SP-DAGs.

Now consider every source (internal or not) \( u_i \) in the SP-ladder. We can enumerate all the potential sinks \( t \) for that source using Lemma VI.3. We know that any cycle from \( u_i \) to \( t \) must have one path that goes across a cross-link \( K_i \) and another path that goes across \( S_i \). We define \( L_s(u_i, t) \) as the length of the shortest directed path from \( u_i \) to \( t \) that goes along \( S_i \) and \( L_k(u_i, t) \) as the length of the shortest directed path from \( u_i \) to \( t \) that goes along \( K_i \). Similarly, \( h_s(u_i, t) \) is the length of the longest directed path (in terms of hop count) from \( u_i \) to \( t \) that goes along \( S_i \) and \( h_k(u_i, t) \) as the length of the longest directed path from \( u_i \) to \( t \) that goes along \( K_i \).

Now consider an edge \( e \) in some constituent SP-DAG \( H \) along the path from \( u_i \) to \( t \). We can update the dummy interval for \( e \) as follows: If \( e \) lies along some path from \( u_i \) to \( t \) that goes across \( K_i \), then \( [e] = L_s(u_i, t)/h_k(u_i, t) - h(H) + h(H, e) \). If on the other hand, \( e \) lies along some path from \( u_i \) to \( t \) that goes across \( S_i \), then \( [e] = L_k(u_i, t)/h_s(u_i, t) - h(H) + h(H, e) \). We can do the analogous procedure for each potential source \( u_i \).

Running Time: There are \( O(|G|^2) \) source-sink pairs. For a given pair \( u_i \) and \( t \), we can calculate \( L_s(u_i, t) \), \( L_k(u_i, t) \), \( h_s(u_i, t) \) and \( h_k(u_i, t) \) using \( L \) and \( h \) values of the constituent SP-DAGs in \( O(|G|) \) time. We can also update all dummy intervals for edges on some path from \( u_i \) to \( t \) in \( O(|G|) \) time. Therefore, the overall algorithm takes \( O(|G|^3) \) time.

VII. CONCLUSION

In this work, we have explored the practicality of a flexible, general model of streaming computation. This model, formalized by us, permits computation nodes to arbitrarily filter their inputs. We have shown that, if the allowed streaming topologies are restricted to the CS4 DAGs (or, more stringently, to the SP-DAGs), then we can efficiently parametrize our dummy message-based deadlock avoidance algorithms. Hence, if the streaming application programmer agrees to use such topologies, the compiler and runtime system can guarantee safe execution of the resulting applications, in a way that is non-intrusive to application code and that scales even to large and complex applications.

Our work raises several directions for future research. One open question is whether it is possible to reduce the frequency of dummy messages sent in CS4 graphs below that mandated by deadlock avoidance for general DAGs. It may be that the simpler structure of these DAGs allows not just more efficient implementation of our avoidance scheme but a new, lower-bandwidth scheme altogether. A second question is whether one can efficiently translate arbitrary DAGs to equivalent CS4 topologies by adding a small number of nodes and edges. For example, the butterfly of Figure 4 can be replaced by an SP-ladder with cross-links a-d and d-c, provided that data to be sent from b to c is routed via an extra hop through d. Finally, we plan to augment an existing language for streaming computation, such as the X language [12], to support the filtering model.
