**ABSTRACT**

The challenge of osmotic stress is something all living organisms must face as a result of environmental dynamics. Over the past three decades, innovative research and cooperation across disciplines has irrefutably established that cells utilize mechanically gated ion channels to release osmolytes and prevent cell lysis during hypoosmotic stress. Early electrophysiological analysis of the inner membrane of *Escherichia coli* identified the presence of three distinct mechanosensitive activities. The subsequent discoveries of the genes responsible for two of these activities, the mechanosensitive channels of large (MscL) and small (MscS) conductance, led to the identification of two diverse families of mechanosensitive channels. The latter of these two families, the MscS family, is made up of members from bacteria, archaea, fungi, and plants. Genetic and electrophysiological analysis of these family members has provided insight into how organisms use mechanosensitive channels for osmotic regulation in response to changing environmental and developmental circumstances. Furthermore, solving the crystal structure of *E. coli* MscS and several homologs in several conformational states has contributed to the understanding of the gating mechanisms of these channels. Here we summarize our current knowledge of MscS homologs from all three domains of life, and address their structure, proposed physiological functions, electrophysiological behaviors, and topological diversity.

## INTRODUCTION

### I. Ion Channels

Ion channels are membrane-spanning protein complexes that form a gated macromolecular pore. An open channel can facilitate the passive diffusion of tens of millions of ions per second from one side of the membrane to the other, down their electrochemical gradient <sup>1, 2</sup>. The role played by ions in the excitable membranes of muscle and nerve cells has been studied for over a hundred years <sup>3</sup> and the importance of ion channels as mediators of the nervous system and their role in human disease is now well established (several recent reviews include <sup>4-6</sup>). However, plant and microbial ion channels have also been important subjects of study <sup>7, 8</sup>. It is often forgotten that single-cell action potentials were first described in the giant cells of characean algae and that during the 1930s, the excitation of squid axons and algal membranes was studied side-by-side (reviewed in <sup>9-11</sup>). The bacterial potassium crystallographically-sited activation channel (KcsA) was the first ion channel to be characterized by X-ray crystallography <sup>12</sup>, and it is now understood that bacteria have a wide array of ion-specific, mechanosensitive, and water channels <sup>13</sup>. Investigations into plant and microbial ion channels not only inform our understanding of basic cellular physiology, but may also be instrumental in engineering defenses against microbial pathogens and in crop improvement <sup>14, 15</sup>.

Ion channels can be classified according to homology-based family groupings or behavioral characteristics such as ion selectivity or gating stimulus (in addition to other more subtle behaviors such as conductance, adaptation and opening or closing kinetics). Many channels are specific to the ion or small molecule that they allow to pass (KcsA has a 1000-fold preference for K<sup>+</sup> over Na<sup>+</sup> ions <sup>16</sup>), while others are not (the bacterial mechanosensitive ion channel of large conductance (MscL) has no ionic preference at all <sup>17</sup>). Channel conductance, the ease with which current passes from one face of the channel pore to the other, can range over several orders of magnitude in different channel types and organisms. For example, the aforementioned MscL has one of the largest conductances measured, up to 3

1  
2  
3  
4 nS<sup>17</sup>, while the small potassium (SK) channels associated with Parkinson's disease have a conductance of  
5  
6 only 10 pS<sup>18</sup>. The burst of ion flux that results from the rapid opening of an ion channel (occurring on the  
7  
8 order of milliseconds) can have several downstream effects: a change in membrane potential, which can  
9  
10 serve as a signal itself by exciting other channels; a burst of intracellular Ca<sup>2+</sup>; or the normalization of ion  
11  
12 concentrations across a membrane to control cell volume. Ion channels open (or "gate") only under  
13  
14 certain conditions, such as altered transmembrane voltage, binding of a small ligand, or mechanical force.  
15  
16 It is one family of channels that respond to the latter stimulus, called mechanosensitive (MS) channels,  
17  
18 which we consider in this review.  
19

21

## 22 **II. Mechanosensitive Ion Channels**

### 23 A. Gating Models

24  
25  
26 How force administered to a cell is delivered to a mechanosensitive channel, and how the channel  
27  
28 subsequently converts that force into ion flux are important questions requiring the purposeful integration  
29  
30 of genetic, biochemical, structural, and biophysical approaches. Three simplified models have been  
31  
32 proposed for the gating of channels that act directly as mechanoreceptors (that is, there is not an  
33  
34 intermediary between the force perception and the channel)<sup>19-21</sup>. These models are described below and  
35  
36 illustrated in Figure 1.  
37  
38  
39

40  
41 **Intrinsic.** In the intrinsic bilayer model (Fig. 1A), force is conveyed to the channel directly through  
42  
43 the planar membrane in which it is embedded, and lipid-protein interactions are the primary determinants  
44  
45 of the favored state. Biophysical modeling approaches have indicated that the closed state of the channel  
46  
47 is favored under low membrane tensions due to the cost of membrane deformation at the perimeter of the  
48  
49 channel. A channel can deform the surrounding membrane due to mismatch between the thickness of the  
50  
51 membrane and the thickness of the hydrophobic domain of the channel. In addition, the membrane (which  
52  
53 has a lower compressibility modulus than the channel<sup>22</sup>) can be locally distorted or bent as it conforms to  
54  
55 the shape, or profile, of the embedded channel<sup>20, 23, 24</sup>. The energy cost associated with these membrane  
56  
57  
58  
59  
60

1  
2  
3  
4 deformations increases upon channel opening, as the cross-sectional area—and therefore the perimeter—  
5  
6 of the channel expands. However, loading the membrane with tension through a patch pipette or osmotic  
7  
8 pressure can offset this energy cost; under these conditions the open state is favored. Importantly,  
9  
10 membranes are active participants in the gating of MS channels and the pressure exerted by the lipid on  
11  
12 the channel is a critical component of the intrinsic bilayer model <sup>25</sup>. This model is supported by  
13  
14 experimental evidence showing that the fluidity, thickness and curvature of the membrane influence the  
15  
16 gating characteristics of MS channels <sup>26-28</sup>.  
17  
18

19  
20 **Tethered.** It has long been speculated that mechanotransduction by hair cells of the vertebrate inner  
21  
22 ear is mediated by the action of tethers (called “tip links”) on transducer channels located in the hair cell  
23  
24 plasma membrane (reviewed in <sup>29</sup>). In the tethered trapdoor model (Fig. 1B), force is conveyed to the  
25  
26 channel through tension applied to other cellular components, such as the actin or microtubule  
27  
28 cytoskeleton and/or the extracellular matrix. Displacement of the cellular component pulls on the channel  
29  
30 through the tether, thereby triggering its opening. Alternatively, it has been proposed that rather than  
31  
32 opening a trapdoor, pulling a tether leads to reorientation of the channel within the lipid bilayer, which  
33  
34 results in channel gating in response to the membrane deformation and tension forces described above  
35  
36 (Fig. 1C) <sup>21, 30, 31</sup>. In this “unified” model, as with the intrinsic bilayer model, the biophysical properties of  
37  
38 the membrane are an important contributor to the lowest energy conformation of a MS channel, and can  
39  
40 either restrict or facilitate changes in state.  
41  
42  
43  
44

#### 45 B. Electrophysiology and Model Systems

46  
47

48 The first observations of ion flux in response to mechanical stimuli quickly followed the development  
49  
50 of the patch-clamp technique in the mid-1980s. This technique allows one to record the current passing  
51  
52 across a small patch of membrane tightly sealed to the tip of a thin glass capillary pipette (reviewed in <sup>32</sup>).  
53  
54 A key aspect of this technique is the formation of a high resistance “gigaseal” between the membrane and  
55  
56 the glass (on the order of 1GOhm or higher). When positive or negative pressure is applied to the  
57  
58  
59  
60

1  
2  
3  
4 membrane patch through this glass recording pipette, the membrane (and any associated cytoskeletal  
5  
6 components) is deformed. The opening and closing of individual mechanically gated ion channels can  
7  
8 then be observed over time <sup>33, 34</sup>. Early patch-clamping experiments resulted in the identification of  
9  
10 stretch-activated ion channels in animal cells known to be specialized for mechanical perception <sup>35-38</sup>.  
11  
12 Similar activities were soon identified in non-specialized cells <sup>36, 39</sup>, leading to the proposal that sensitivity  
13  
14 to mechanical stimuli might be a basic cellular feature <sup>22, 40</sup>. In the decades since these first studies, many  
15  
16 families of MS channels have been identified and characterized in bacteria, plants, animals, and archaea  
17  
18 (reviewed in <sup>41-43</sup>). MS channels can be activated by membrane tension introduced through the patch  
19  
20 pipette as described above, by the swelling associated with hypo-osmotic shock, or by treatment of cells  
21  
22 with membrane-bending amphipaths. Their function has been investigated in endogenous membranes, in  
23  
24 a variety of heterologous systems, and even reconstituted into artificial membranes. Leading the way in  
25  
26 many of these studies is a suite of bacterial channels, arguably the best studied and best-understood  
27  
28 mechanoperceptive proteins at the functional, structural, and biophysical levels.  
29  
30  
31  
32

### 33 34 **III. *E. coli* MscL, MscS, and MscM**

#### 35 36 A. Identification

37  
38 Identifying MS channels in bacteria by electrophysiological analysis at first presented several  
39  
40 challenges as an *E. coli* cell is smaller than the diameter of a typical patch pipette tip, and has a  
41  
42 peptidoglycan layer between the inner and outer membranes <sup>44, 45</sup>. This problem was solved by treating  
43  
44 cultures with an inhibitor of cell division and then enzymatically digesting the peptidoglycan layer. These  
45  
46 treatments result in the production of “giant *E. coli* protoplasts” amenable to patch clamp  
47  
48 electrophysiology <sup>46</sup>. Using this approach, the Kung group measured current induced in response to  
49  
50 membrane stretch in *E. coli* and observed a robust tension-sensitive channel activity <sup>44</sup>. Subsequent  
51  
52 studies established that at least three distinct channel activities are detectable in the inner membrane of *E.*  
53  
54 *coli*—the mechanosensitive channels of large, small, and mini conductances. MscL, MscS, MscM  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 activities each have different conductances (3 nS, 1 nS and 0.3 nS, respectively) and are activated at  
5  
6 decreasing thresholds of pressure <sup>17, 47-49</sup>.

### 7 8 B. Cloning

9  
10 It is now established that the three classic activities of the *E. coli* membrane, MscL, MscS and MscM,  
11  
12 represent a complex combination of activities provided by two distinct families of MS channels. The *E.*  
13  
14 *coli mscL* gene was cloned through a fractionation/reconstitution and microsequencing strategy <sup>50</sup> and  
15  
16 found to be essential for MscL activity. The *mscS/yggB* gene was identified through a combination of  
17  
18 forward and reverse genetic approaches, and along with *mscL* is underlies the primary response of an *E.*  
19  
20 *coli* cell to rapid increases in membrane tension <sup>51</sup>. While the MscS and MscL proteins are structurally  
21  
22 and evolutionarily unrelated, at least part of the originally observed MscS activity can now be attributed  
23  
24 to the action of another channel with homology to MscS, now referred to as kefA/MscK <sup>52</sup> (for more on  
25  
26 MscK, see below). When either MscL <sup>50</sup> or MscS <sup>53</sup> monomers are purified, assembled into channels, and  
27  
28 reconstituted into artificial liposomes, both show characteristics indistinguishable from that in native *E.*  
29  
30 *coli* membranes, indicating that neither requires additional cellular structures for mechanosensitivity.  
31  
32 Thus, both MscS and MscL are gated in direct response to lipid bilayer deformation, as in the intrinsic  
33  
34 bilayer model (Fig. 1A). Relatively less is known about MscM, though recent reports have demonstrated  
35  
36 that YjeP and YbdG, two more homologs of MscS, are likely to underlie this elusive activity <sup>54, 55</sup>.

### 37 38 C. Physiological Function

39  
40 Bacterial cells are found in a variety of dynamic environments, frequently requiring them to adapt to  
41  
42 changing osmotic conditions. In order to maintain turgor pressure during exposure to hyperosmotic stress,  
43  
44 bacterial cells accumulate osmolytes that are compatible with cellular metabolism <sup>56</sup>. On the other hand, a  
45  
46 sudden shift to hypoosmotic conditions will cause a rapid influx of water across the lipid bilayer, leading  
47  
48 to increased membrane tension (reviewed in <sup>34, 57</sup>). It has been estimated that a mere 20 mM drop in  
49  
50 external osmolarity can result in membrane tensions that approach lytic levels if unrelieved <sup>34</sup>. A  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 hypoosmotic shock of this type might occur when soil bacteria are caught in the rain, when marine  
5  
6 bacteria migrate to freshwater or during the transmission of pathogenic bacteria through excrement.  
7  
8 Without a rapid response, these shocks would lead to a compromised cell wall, leaving the cell vulnerable  
9  
10 to lysis <sup>58</sup>.

11  
12  
13 It had long been proposed that bacterial cells were capable of relieving this type of environmental  
14  
15 hypoosmotic stress by facilitating the exit of osmolytes from the cell, thus ensuring the physical integrity  
16  
17 of the cell under increased turgor <sup>45, 56, 59</sup>. We now know that the primary mechanism for hypoosmotic  
18  
19 shock survival is the activation of MS channels, which allows the passive diffusion of nonspecific  
20  
21 osmolytes out of the cell, relieving membrane tension and preventing cellular lysis. *E. coli* strains with  
22  
23 lesions in both *mscL* and *mscS* show reduced survival of hypoosmotic shock though single mutations have  
24  
25 no discernable effect <sup>50, 51</sup>. Mutants lacking YbdG also show a small defect in osmotic shock survival <sup>54</sup>  
26  
27 and the overexpression of YjeP promotes survival in the absence of all other MS channels <sup>55</sup>. Thus, these  
28  
29 bacterial MS channels are often referred to as osmotic “safety valves” <sup>60</sup> and have been proposed to  
30  
31 provide a graded series of responses allowing the bacteria to tune its response to different osmotic  
32  
33 challenges under different environmental or developmental conditions <sup>13, 45, 48, 52, 61</sup>.

#### 34 35 36 37 38 39 40 41 **MSCS and MSCS-LIKE CHANNELS: CONSERVATION AND DIVERSITY**

42  
43 These classic mechanosensitive channels from *E. coli* described above not only serve important  
44  
45 biological functions, but MscL and MscS have also become leading model systems for the study of MS  
46  
47 channel structure and function. Here we focus on the structure and function of the bacterial  
48  
49 mechanosensitive channel MscS and its homologs in *E. coli*, other microbes, and in eukaryotes. Several  
50  
51 excellent reviews on MscL have recently been published <sup>57, 62, 63</sup>.

#### 52 53 54 55 **I. Structure**

1  
2  
3  
4 Crystallographic studies of MscS structure are beginning to answer the fundamental question of how  
5  
6 mechanosensitivity is accomplished in MscS-type channels (recently reviewed in <sup>64</sup>). At present, five  
7  
8 structures of prokaryotic MscS homologs have been solved: wild type *E. coli* MscS (*EcMscS*) in both  
9  
10 open and nonconducting (not necessarily closed, see below) conformations <sup>65-67</sup>, a point mutation of  
11  
12 *EcMscS* that likely represents the open conformation, and MscS homologs from *Thermoanaerobacter*  
13  
14 *tengcongensis* (*TtMscS*)<sup>68</sup> and *Helicobacter pylori* (*HpMscS*)<sup>65</sup> in nonconducting conformations. Four of  
15  
16 these structures are shown in Figure 2. A cartoon representation of each is shown from the side (left  
17  
18 panel), and both cartoon and space-filling models are shown from the periplasmic surface (middle and  
19  
20 right panels). A fragment containing the three TM domains and the upper vestibule from a single  
21  
22 monomer of each of these structures (including amino acids 27-175 for *EcMscS*) is shown in Figure 3.  
23  
24 Despite the inevitable possibility of artifacts associated with packing contacts and protein-detergent  
25  
26 interactions <sup>21, 69, 70</sup>, these structures provide an invaluable source of information about the molecular  
27  
28 mechanism of gating and the relationship between channel structure and electrophysiological behavior.  
29  
30  
31  
32

#### 33 A. Nonconducting and Open Conformations of *EcMscS* and Homologs

34  
35  
36 **Nonconducting Conformations.** The first crystal structure of *EcMscS* was solved by the Rees group  
37  
38 at 3.7 Å resolution <sup>66, 67</sup> (Fig 2A) and revealed a homoheptameric channel with three transmembrane alpha  
39  
40 helices per monomer and a large, soluble C-terminal domain. This oligomeric state and topology were  
41  
42 subsequently verified experimentally <sup>71-73</sup>. As shown in Figure 3, each monomer contributes three tightly  
43  
44 packed N-terminal transmembrane (TM) alpha helices to the transmembrane region. TM1 (residues 28 -  
45  
46 60) and TM2 (residues 63 - 90) face the membrane, while TM3 (residues 93 - 128) lines the channel pore.  
47  
48 (The residues assigned to each helix are as in <sup>64</sup>). One striking feature of the structure is a sharp kink at  
49  
50 Q112/G113, which divides TM3 into TM3a, which is roughly perpendicular to the membrane, and TM3b,  
51  
52 which is almost parallel to the membrane (Fig. 3A). The narrowest constriction of the pore has a diameter  
53  
54 of 4.8 Å, and is created by two rings of Leucine residues (L105 and L109) with inward facing side chains.  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 These hydrophobic rings prevent the wetting of the pore and thereby serve as a “vapor lock” to the  
5  
6 movement of ions through the channel <sup>74, 75</sup>. Mutational analysis of L105 confirmed its importance in  
7  
8 maintaining the closed state <sup>71</sup>. The C-terminal region of each monomer contributes to a large hollow  
9  
10 structure referred to here as the “vestibule”. The vestibule comprises seven side portals and one axial  
11  
12 portal located at the base of the vestibule, formed by a seven-stranded  $\beta$ -barrel.  
13  
14

15 Originally thought to be the open conformation, this structure it is now generally agreed to represent a  
16  
17 nonconducting state. It is unlikely to represent the normal closed conformation, because TM1 and TM2  
18  
19 are not in contact with TM3, an expected requirement for tension-sensitive gating (see the section on  
20  
21 “force-sensing” below)<sup>34, 76</sup>. A number of molecular dynamics (MD) simulations further support this  
22  
23 conclusion <sup>74, 77, 78</sup>. The recently reported structures of *TtMscS* (Fig 2B) and *HpMscS* (not shown) exhibit  
24  
25 similar transmembrane helix organization and pore size as the original *EcMscS* structure, and therefore  
26  
27 are also considered to represent nonconducting states <sup>65, 68</sup>. The C-terminal vestibule of *TtMscS* has  
28  
29 several differences in structure from that of *EcMscS*, which are shown to modulate the conducting  
30  
31 properties of the channel and are discussed below.  
32  
33  
34  
35

36 **Open Conformations.** Though invaluable for establishing the basic structure of MscS,  
37  
38 nonconducting structures give limited insight into the channel’s gating mechanism. In a directed attempt  
39  
40 to solve the structure of MscS in an alternate conformation, the Booth and Naismith groups crystalized  
41  
42 the A106V point mutation of *EcMscS* at 3.45 Å resolution <sup>79</sup>, Fig. 2C. The resulting structure has a  
43  
44 substantially increased pore size (approximately 13 Å in diameter) due to a rearrangement of  
45  
46 transmembrane helices. TM1 and TM2 are angled away from TM3b and the channel core, while TM3a is  
47  
48 tilted away from the plane of the membrane and rotated slightly away from the pore (compare Fig 3A and  
49  
50 C). TM3b and the upper vestibule are mostly unchanged compared to the nonconducting structures. These  
51  
52 rearrangements place the vapor-lock residues out of the pore, as previously predicted based on  
53  
54 experimental and modeling data <sup>80-82</sup>. A pulsed electron-electron double resonance (PELDOR) approach <sup>83</sup>  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 revealed that two *EcMscS* mutants, spin-labeled at D67C (PDB 4AGE) or L124C (4AGF), took a similar  
5  
6 conformation in solution, indicating that it is not an artifact of crystal packing nor of the particular A10V  
7  
8 mutation<sup>84</sup>. Further confirmation that the A106V structure properly resembles the open state comes from  
9  
10 a recent report describing wild type *EcMscS* solubilized in a different detergent ( $\beta$ -dodecylmaltoside  
11  
12 instead of fos-choline-14), at a resolution of 4.4 Å (<sup>65</sup> Fig. 3D). This structure closely resembles the  
13  
14 A106V *EcMscS* structure, establishing a solid consensus regarding the open state structure of *EcMscS*.  
15  
16

### 17 B. Gating Mechanism

18  
19  
20 Despite having multiple crystal structures attributed to different states of MscS, as well as an array of  
21  
22 mutational and functional data that have determined functionally important residues, the actual  
23  
24 mechanism of transition between closed and open states is still not completely clear. While several  
25  
26 models have been proposed based on MD simulations<sup>81, 85</sup> and electron paramagnetic resonance (EPR)  
27  
28 spin labeling<sup>82</sup>, the model which is currently favored is one wherein membrane tension induces the  
29  
30 rotation and tilting of TM1 and TM2 as a whole, immersing them more deeply into the surrounding lipid  
31  
32 bilayer. This movement pulls TM3a away from the pore until it's oriented almost normal to the  
33  
34 membrane plane, effectively removing the L105 and L109 vapor lock side chains and opening the channel  
35  
36 to ion flux<sup>64, 79</sup>. In all of the crystal structures described above, the positioning of TM1 and TM2 with  
37  
38 respect to each other is the same, as if they act like a rigid lever (compare Fig 3.A, B to Fig. 3C and D).  
39  
40 Assuming that the newly obtained crystal structures described above indeed represent nonconducting and  
41  
42 open states, the “rigid-body” movement model of transition into the open state may be considered the  
43  
44 most probable.  
45  
46  
47  
48

49  
50 Lipid-protein interactions must occur at the periphery of the channel, which in MscS is likely to be  
51  
52 comprised of TM1 and TM2. Hydrophobic residues in the protein-lipid interface of TM1 and TM2 were  
53  
54 shown in several site-directed mutagenesis studies to affect tension sensitivity and osmotic shock  
55  
56 protection<sup>86, 87</sup>. In addition, an interaction between F68 in TM2 and L111 in TM3 was shown by  
57  
58  
59  
60

1  
2  
3  
4 electrophysiology and mutational analysis to be of critical importance for force transmission from lipid-  
5 facing helices to the pore region; disruption of this inter-helical contact results in channel inactivation<sup>76</sup>.  
6  
7  
8 These data are consistent with a model wherein TM1 and TM2 serve as a tension sensor, transmitting  
9 force from the membrane to TM3; subsequent rearrangement of TM3 helices results in channel gating. It  
10 is intriguing to consider MscS homologs that possess additional N-terminal transmembrane helices (for  
11 several examples, see Figure 4). Additional helices may shield TM2 and TM3 from lipid environment of  
12 membrane or serve as tension sensors themselves, transmitting force to the pore-lining helix through a  
13 different (yet unknown) mechanism<sup>88</sup>.  
14  
15  
16  
17  
18  
19  
20  
21

### 22 C. Contributions by the C-terminus

23  
24  
25 Though the structure of the C-terminal vestibule is virtually unchanged in all the crystal structures  
26 assigned to open and nonconducting states of *EcMscS*, other evidence indicates that this portion of the  
27 channel may be subject to conformational changes during opening, closing and inactivation transitions.  
28  
29  
30  
31  
32  
33  
34  
35  
36  
37  
38  
39  
40  
41  
42  
43  
44  
45  
46  
47  
48  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60  
Analyses of multiple deletion and substitution mutants have established that the vestibule is important for  
channel function and stability<sup>71, 89, 90</sup>, and that interactions between the upper surface of the vestibule and  
the TM domain can affect gating as well as inactivation behavior<sup>91, 92</sup>. Co-solvents that induce  
compaction of the C-terminal domain have been shown to facilitate MscS inactivation<sup>93</sup>, while  
experiments utilizing FRET to quantify the diameter of the cytoplasmic domain showed that it swells  
during gating<sup>94</sup>. Taken together, these data indicate that gross structural remodeling of the vestibule and  
its interactions with the transmembrane domain likely accompanies inactivation and gating cycles.

In addition, recent reports support a role for the C-terminus as an ion selectivity filter. In *EcMscS*,  
ions likely do not enter the vestibule through the axial  $\beta$ -barrel, as the portal that it forms is too narrow  
(1.75 Å in its narrowest part); rather, they probably travel through the seven side portals into the vestibule  
and then cross the pore. MS simulations suggest the vestibule serves to filter and balance charged  
osmolytes prior to their release from the cell, keeping ion efflux largely neutral in charge and thereby

1  
2  
3  
4 preventing membrane depolarization <sup>95</sup>. Another correlation between vestibule structure and ion  
5  
6 selectivity comes from recent studies of *TtMscS* <sup>68</sup>. Compared to *EcMscS*, *TtMscS* has smaller side  
7  
8 portals but a much wider axial portal; at the same time it has a much higher selectivity for anions (see  
9  
10 below for a discussion of ion selectivity). A version of *TtMscS* where the axial  $\beta$ -barrel sequence (amino  
11  
12 acids 271 to 282) was replaced with the corresponding portion of *EcMscS* lost this preference for anions,  
13  
14 indicating that this small portion of the C-terminus can strongly influence overall channel behavior.  
15  
16

#### 17 D. Summary

18  
19  
20 The five independently derived crystal structures of bacterial MscS homologs available to date have  
21  
22 revolutionized our understanding of the overall architecture of bacterial MscS homologs, provided  
23  
24 context for the interpretation of mutagenic data and MD simulations, and established a sophisticated  
25  
26 foundation for furthering our understanding of the gating cycle. We note that no crystal structures have  
27  
28 yet been reported for archaeal or eukaryotic MscS homologs; such a structure would be a major step  
29  
30 forward for those interested in the evolutionary diversification of this family of proteins.  
31  
32

## 33 **II. Evolutionary History**

34  
35  
36 The MscS protein superfamily is vast and diverse, with members found in most bacterial, archeal,  
37  
38 some fungal, and all plant genomes so far analyzed <sup>96-101</sup>. However, MscS family members have not yet  
39  
40 been found in animals. It has been suggested that MS channels first evolved in an ancestor common to all  
41  
42 cell-walled organisms and have been maintained throughout these lineages as a solution to osmotic stress  
43  
44 and regulation of turgor pressure <sup>96, 97, 102</sup>. Another explanation is that the membrane reservoirs of animal  
45  
46 cells allow hypoosmotic swelling without producing membrane tension, or that mammalian membranes  
47  
48 do not stretch due to their close association with the cytoskeleton <sup>103, 104</sup>. Alternatively, MscS homologs  
49  
50 could simply be unrecognizable in animal genomes by current homology-based searches.  
51  
52

53  
54  
55 Mapped onto the MscS structure, the conserved domain comprises the pore-lining helix (in MscS, this  
56  
57 is TM3) and the upper part of the cytoplasmic vestibule. Outside of this domain MscS family members  
58  
59  
60

1  
2  
3  
4 vary greatly in sequence and topology. The number of predicted TM helices for MscS family members  
5  
6 ranges from 3 to 12 and a variety of conserved domains, including those associated with the binding of  
7  
8  $\text{Ca}^{2+}$  and cyclic nucleotides, have been identified in some subfamilies<sup>51, 96, 105, 106</sup>. Furthermore, multiple  
9  
10 MscS homologs are frequently identified within a single organism (including many bacterial and all plant  
11  
12 genomes analyzed to date), suggesting that functional specialization of MscS homologs has evolved both  
13  
14 and within a single organism. Our current understanding of the physiological function of MscS homologs  
15  
16 from bacteria, fungi, plant cells and plant organelles is described below and summarized in Table 1.  
17  
18  
19

### 20 **III. Physiological Function**

21  
22 While it has been clearly established that MscL and MscS serve to protect cells from extreme  
23  
24 environmental hypoosmotic shock, it is becoming evident that the functions of the members of this family  
25  
26 may be more complex. An emerging theme is that MscS homologs have evolved specific functions  
27  
28 tailored to the needs of the organism, including the release of specific cellular osmolytes in response to  
29  
30 specific environmental or developmental osmotic triggers.  
31  
32

#### 33 A. Prokaryotes

34  
35  
36 *E. coli*. We know by far the most about the six MscS family members encoded in the *E. coli* genome  
37  
38 (MscS, MscK, YjeP, YbdG, YbiO, and YnaI)<sup>51</sup>. Research into their physiological roles suggests that they  
39  
40 all serve to release osmolytes from the cell under hypoosmotic stress but that their function is only  
41  
42 required for cell viability under specific conditions. Even MscS may serve specialized roles, as MscS  
43  
44 protein levels fluctuate. MscS levels are elevated during growth at high osmolarity, possibly a preemptive  
45  
46 method of dealing with an impending downshock, and during stationary phase, perhaps to deal with the  
47  
48 osmotically vulnerable state of cell wall remodeling<sup>107, 108</sup>. MscK contributes modestly to cell survival  
49  
50 during standard osmotic shock assays (Levina 1999; McLaggan et al., 2002 *Molecular Microbiology* and  
51  
52 Li et al., 2002 *EMBO*) and its mechanosensitive channel activity requires the presence of  $\text{K}^+$  ions in the  
53  
54 extracellular solution. It has been proposed that binding of  $\text{K}^+$  primes the channel for gating. Such an  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 activity may be required for survival in soils with high concentrations of animal urine or within the  
5  
6 kidneys during host infection <sup>109</sup>. The remaining *E. coli* MscS family members (YbdG, YjeP, YbiO and  
7  
8 YnaI) can provide osmotic shock protection when overexpressed in *E. coli* <sup>54, 55</sup>, and the latter three  
9  
10 activities may simply be expressed at too low levels to contribute under normal laboratory assay  
11  
12 conditions. Indeed, the occurrence of the previously uncharacterized 20 pA  
13  
14 mechanosensitive channel activity attributed to YbiO increased dramatically when cells were treated with  
15  
16 NaCl prior to patching <sup>55</sup>.

17  
18  
19  
20 **Other species.** The 3 MscS homologs (*yhdY*, *yfkC*, and *yukT*) of the gram-positive bacterium *B.*  
21  
22 *subtilis* are dispensable for osmotic shock survival in the laboratory, though the *mscL yukT* double  
23  
24 mutant strain exhibits enhanced osmotic sensitivity compared to the *mscL* single deletion strain <sup>110-112</sup>. As  
25  
26 *B. subtilis* is found in both the soil and the human gut, there may be specific growth conditions wherein  
27  
28 these MscS homologs contribute to osmotic homeostasis that are not replicated in the laboratory  
29  
30 environment. Other prokaryotic MscS homologs have been identified that provide tantalizing ideas about  
31  
32 the variety of ways in which this family of channels may have evolved to provide osmotic adjustment in  
33  
34 response to different environmental and developmental stimuli. The gram-positive bacterium  
35  
36 *Corynebacterium glutamicum* is used in the industrial production of glutamate and other amino acids <sup>113</sup>.  
37  
38 Its genome encodes homologs of both MscL and MscS (MscCG/NCgl1221), but neither is required for  
39  
40 cell survival in laboratory-based osmotic downshock assays <sup>114, 116</sup>. Instead, MscCG is involved in  
41  
42 regulating the steady state concentration of glycine betaine (the preferred compatible osmolyte of *C.*  
43  
44 *glutamicum*) in response to both hypo- and hyperosmotic stress <sup>115</sup>. MscCG is also essential for glutamate  
45  
46 efflux in response to biotin limitation and penicillin treatment, notably in the absence of hypoosmotic  
47  
48 stress <sup>116, 118</sup>. Several lines of evidence, including the analysis of loss-of-function and gain-of-function  
49  
50 lesions in the predicted pore-lining helix, support the model that MscCG directly mediates the efflux of  
51  
52 glutamate and that this efflux is dependent on mechanosensitive channel gating <sup>116-119</sup>. Thus, MscCG is  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 likely a mechanically gated MscS homolog that is involved in osmotic adjustment of specific compatible  
5  
6 solutes in response to multiple stimuli.  
7

8  
9 Finally, there are indications that MscS family members are important for pathogenesis and  
10  
11 metabolism, perhaps indicating the importance of osmotic adjustment in these processes. Two MscS  
12  
13 homologs from the food-borne pathogen *Campylobacter jejuni*, *Cjj0263* and *Cjj1025*, were recently  
14  
15 found to be required for colonization of the digestive tract of chicks <sup>120</sup>, and a *Pseudomonas aeruginosa*  
16  
17 MscK ortholog has been associated with virulence <sup>121</sup>. PamA, a MscS homolog from the photosynthetic  
18  
19 cyanobacterium *Synechocystis* sp.PCC6803 was reported to interact in vitro and in vivo with PII, a highly  
20  
21 conserved carbon/nitrogen sensor <sup>122, 123</sup>. Furthermore, nitrogen response and sugar metabolic genes show  
22  
23 altered expression in the absence of *PamA*, suggesting that it may serve to integrate carbon and nitrogen  
24  
25 metabolism with osmotic conditions. Taken together, these preliminary studies illustrate how much more  
26  
27 has yet to be revealed regarding MscS homolog function in the prokaryotic world.  
28  
29  
30

### 31 32 B. Eukaryotes

33  
34 While less studied than their prokaryotic counterparts, recent research offers a few glimpses into the  
35  
36 important functions and novel characteristics of the eukaryotic members of the MscS family. Sequence  
37  
38 similarities place them into two major classes (described in <sup>98</sup>). Class II members are predicted to localize  
39  
40 to the plasma membrane or intracellular membranes of both plants and fungi. Class I channels, which  
41  
42 show slightly more sequence conservation to MscS than those in class II, are predicted to localize to  
43  
44 endosymbiotic organelles (mitochondria and plastids such as chloroplasts), and are found only in plant  
45  
46 genomes.  
47  
48

49  
50 **Class I.** Considering the origin of endosymbiotic organelles (the engulfment of a primitive bacterium),  
51  
52 the MscS homologs found in their envelopes are likely to have a conserved function as osmotic safety  
53  
54 valves, but in this case protecting mitochondria and plastids from fluctuations in intracellular rather than  
55  
56 extracellular osmotic concentrations <sup>15</sup>. The Mechanosensitive Channel (MSC)1, from *Chlamydomonas*  
57  
58  
59  
60

1  
2  
3  
4 *reinhardtii* localizes to punctate spots associated with the single plastid found in these cells, and plastid  
5  
6 integrity is lost when the *MSC1* gene is silenced by RNAi (Nakayama 2007). To date, MSC1 is the only  
7  
8 Class I MscS homolog to be successfully characterized by electrophysiology (see below). Like MSC1,  
9  
10 MscS-Like (MSL)2 and MSL3 of *Arabidopsis thaliana* localize to distinct foci in the plastid envelope.  
11  
12 These two land plant Class I homologs are required for normal plastid shape and size and for proper  
13  
14 placement of the plastid division ring<sup>124, 125</sup>. Proteins involved in the regulation of division site placement  
15  
16 are often conserved between plastids and bacteria, and abnormal division ring placement in an *E. coli*  
17  
18 strain lacking MscL, MscS, and MscK suggest that this may hold true for MS channels as well<sup>125, 126</sup>. The  
19  
20 large, round plastid phenotype of the *msl2 msl3* mutant can be suppressed by a variety of genetic and  
21  
22 environmental treatments that increase cytoplasmic osmolyte levels, indicating that plastids are under  
23  
24 hypoosmotic stress from within the cytoplasm and that MSL2 and MSL3 are required to relieve that stress  
25  
26  
27  
28  
29<sup>127</sup>. Several Class I MscS homologs from land plants are predicted to localize to the mitochondria<sup>98, 101</sup>,  
30  
31 but their study has not yet been reported.  
32  
33

34 **Class II.** The identification of MscS homologs in plant genomes<sup>96, 97</sup> was exciting for plant biologists  
35  
36 because it provided candidate genes for the MS channel activities already known to be widespread in  
37  
38 plant membranes<sup>98</sup>. However, while the *Arabidopsis* genome contains seven MSL proteins that are  
39  
40 predicated to localize to the plasma membrane, and they exhibit distinct tissue-specific expression  
41  
42 patterns<sup>96, 98</sup>, a clear physiological function has yet to be assigned to any (though MSL10 has been  
43  
44 characterized by patch-clamp electrophysiology, see below). The recent characterization of two  
45  
46 endoplasmic reticulum-localized MscS homologs from *Schizosaccharomyces pombe*, Msy1 and Msy2,  
47  
48 suggests that these channels may serve as hypoosmotic stress signaling molecules as much as osmotic  
49  
50 safety valves<sup>105</sup>. *msy1- msy2-* mutant cells exhibit greater swelling and higher Ca<sup>2+</sup> influx upon  
51  
52 hypoosmotic shock, and are more likely to subsequently undergo cell death. Consistent with this idea, we  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 have proposed that MSL10 could play a role in hypoosmotic stress signal transduction through membrane  
5  
6 depolarization <sup>128</sup>.

### 7 8 C. Summary

9  
10 To conclude, current evidence indicates that members of the MscS superfamily exhibit unique forms  
11  
12 of regulation and variations of function. While all are variations on a common theme—action as an  
13  
14 osmotic conduit in response to membrane tension—the proteins within this family may have become as  
15  
16 diverse as the organism in which they reside. We anticipate that more precise analyses, under diverse  
17  
18 growth conditions and at the single cell or organellar level, will reveal the role played by these channels  
19  
20 in the osmotic homeostasis of cells and organelles.  
21  
22  
23

## 24 25 **IV. Electrophysiological Behavior**

26  
27 Besides *EcMscS*, many MscS superfamily members have been shown to be mechanosensitive,  
28  
29 including five others from *E. coli* (*MscK*, *YbdG*, *YnaI*, *YjeP*, and *YbiO*)<sup>54, 55, 109</sup> and three from other  
30  
31 bacterial species (*TmMscS* from *Thermobacter tengcongensis*<sup>68</sup>, *MscSP* from *Silicibacter pomeroyi*<sup>129</sup>,  
32  
33 and *MscCG* from *Corynebacterium glutamicum*<sup>115</sup>. Two MscS homologs from the archaea  
34  
35 *Methanococcus jannaschii*, *MscMJ*, and *MscMJR* have been characterized<sup>102, 130</sup>, as have two channels  
36  
37 from photosynthetic eukaryotes (*MSC1* from *Chlamydomonas reinhardtii* and *MSL10* from *Arabidopsis*  
38  
39 *thaliana*<sup>128, 131</sup>. Despite striking differences in topology and sometimes very low sequence identity, these  
40  
41 channels demonstrate surprisingly conserved behavior in many aspects. Their major characteristics are  
42  
43 shown in Table 2 and discussed in further detail below. Not included here are possible MscS-like  
44  
45 channels from *B. subtilis*<sup>132</sup>, *S. faecalis*<sup>133</sup>, and the bCNG family<sup>106</sup>.  
46  
47  
48  
49

### 50 51 A. Conductance and Ion Selectivity

52  
53 While *MscL* forms a large, completely nonselective pore, *MscS* is slightly anion-selective, preferring  
54  
55  $\text{Cl}^-$  ions over  $\text{K}^+$  ions by a factor of as much as 3 ( $P_{\text{Cl}^-} : P_{\text{K}^+} = 1.2 - 3$ <sup>53, 109, 134, 135</sup>). *MscSP* closely  
56  
57 resembles *EcMscS* in sequence and in channel characteristics with a 1 nS single-channel conductance and  
58  
59  
60

1  
2  
3  
4 P<sub>Cl<sup>-</sup></sub> : P<sub>K<sup>+</sup></sub> = 1.4<sup>129</sup>. MscK also has a conductance close to that of MscS<sup>51, 109</sup>. However, some variation  
5  
6 is observed among the bacterial channels, with a smaller conductance typically associated with more  
7  
8 selectivity. MscCG has a single-channel conductance of 0.3 nS, about one-third the size of that provided  
9  
10 by *Ec*MscS, and prefers cations (P<sub>Cl<sup>-</sup></sub> : P<sub>K<sup>+</sup></sub> = 0.3)<sup>115</sup>. YjeP has a similar conductance, and is also likely to  
11  
12 have a preference for cations, as this was the early characterization of MscM activity (P<sub>Cl<sup>-</sup></sub> : P<sub>K<sup>+</sup></sub> = 0.4).  
13  
14 However, the ion selectivity of YjeP has not yet been assessed directly<sup>48, 55</sup>. As described above, *Tt*MscS  
15  
16 has a single-channel conductance approximately half that of *Ec*MscS and is more strongly anion-selective  
17  
18 (P<sub>Cl<sup>-</sup></sub> : P<sub>K<sup>+</sup></sub> = 8.7)<sup>68</sup>.  
19  
20  
21

22  
23       Though few archaeal or eukaryotic channels have yet been studied, what we know so far indicates a  
24  
25 range of conductances and selectivities similar to those described for bacterial channels. MscMJ (270 pS)  
26  
27 and MscMJLR (2 nS) vary considerably in conductance, but both exhibit a similar preference for cations  
28  
29 (P<sub>Cl<sup>-</sup></sub> : P<sub>K<sup>+</sup></sub> = 0.16 and 0.2, respectively)<sup>102, 130</sup>. Msc1 and MscL10 are quite similar: both have  
30  
31 conductances around a third of that of MscS under similar conditions and both show a preference for  
32  
33 anions (P<sub>Cl<sup>-</sup></sub> : P<sub>K<sup>+</sup></sub> = 7 and 6, respectively)<sup>128, 131, 136</sup>. Once additional homologs are characterized, it can be  
34  
35 determined if these particular examples are characteristic of archaeal and eukaryotic channels. Given the  
36  
37 wide range of sequence similarity in the pore region it is perhaps surprising how similar the MscS  
38  
39 homologs described are: all of them have weak to moderate ionic preferences and a single-channel  
40  
41 conductance which falls approximately into a 4-fold range (under similar conditions, see Table 1 for  
42  
43 details).  
44  
45  
46

#### 47 B. Gating tension

48  
49  
50       MscL is gated by tensions that are close to lytic, and is often used as an internal reference for other  
51  
52 mechanosensitive channels. The threshold tension for activation of MscS, MscK, YjeP and MscCG  
53  
54 activity is approximately one half of that of MscL (MscL : MscS = 1.6, MscL : MscK = 1.9 - 2.2, MscL :  
55  
56 YjeP = 1.6)<sup>51, 55, 109, 118, 137</sup>. Unexpectedly, YnaI and YbiO are gated by tensions almost as high as for  
57  
58  
59  
60

1  
2  
3  
4 MscL<sup>55</sup>. MscSP is less tension-sensitive than MscS and its threshold activation ratio MscL : MscSP was  
5  
6 reported to be 1.28<sup>129</sup>. For the archaeal channels it was found that MscMJ is gated at intermediate  
7  
8 tensions (MscL : MscMJ = 1.3) and MscMJLR at lower tensions (MscL : MscMJLR = 2.5)<sup>102, 130</sup>. If the  
9  
10 tension at which a MS channel gates can be considered an indication of the stimuli to which the channel  
11  
12 has evolved to respond, it seems likely that MscS homologs from different species respond to the same  
13  
14 type of stimulus, as in general they share similar gating thresholds.  
15  
16

### 17 C. Inactivation and desensitization

18  
19  
20 Models of the MscS activation cycle typically include four distinct states: open, closed, inactive and  
21  
22 desensitized<sup>51, 93, 137, 138</sup>. The latter three states are distinct: in the closed state the channel can easily be  
23  
24 gated by threshold tension. In the inactive state, the channel cannot make a transition to the open state  
25  
26 under any tension, while a desensitized channel could be gated by the application of increased tension.  
27  
28 However, for a channel subjected to a fixed membrane tension, the effects of inactivation and  
29  
30 desensitization are indistinguishable and manifest themselves as sharp or gradual current decay in patch-  
31  
32 clamp recordings. In this case, the terms “inactivation” and “desensitization” are often used  
33  
34 interchangeably. While inactivation and/or desensitization under sustained membrane tension have been  
35  
36 reported for MscS expressed in several systems<sup>85, 136, 137</sup>, MscSP, MscCG, MscK, MscMJ and MscMJLR  
37  
38 do not desensitize<sup>51, 102, 109, 115, 129, 130</sup>. MSL10 does not show any significant signs of inactivation<sup>128</sup>, while  
39  
40 MSC1 inactivates at positive membrane potentials, but not at negative<sup>131</sup>. These results leave unclear the  
41  
42 physiological relevance of inactivation<sup>57</sup>.  
43  
44  
45  
46  
47

### 48 D. Hysteresis

49  
50 Another feature of mechanosensitive channel behavior is hysteresis, or a difference between the  
51  
52 tensions required for opening and closing. In the case of MscS, which is routinely observed to close at  
53  
54 higher tensions than at which it opened (summarized in<sup>52</sup>), this phenomenon was at least partially  
55  
56 attributed to the artifacts of membrane patch structure<sup>139</sup>. The eukaryotic channels MSC1 and MSL10  
57  
58  
59  
60

1  
2  
3  
4 also show hysteresis, but of a different type. These channels typically close at a lower tension than at  
5  
6 which they opened. Strikingly, a subpopulation of both types of channels often is observed to stay open  
7  
8 even after all membrane tension has been released <sup>128, 131</sup>. There are no reports of any functional  
9  
10 importance attributed to this phenomenon, but the continuous slow depolarization of the membrane due to  
11  
12 channels staying open after membrane tension is relieved could result in the gating of depolarization-  
13  
14 activated channels and/or the propagation of a systemic signal.  
15  
16

### 17 18 E. Summary

19  
20 Despite limited sequence identity, the MscS family members so far characterized share similar basic  
21  
22 channel characteristics such as conductance and ion selectivity. Other behaviors observed under patch  
23  
24 clamp, such as hysteresis and inactivation/desensitization, are more variable and unclear physiological  
25  
26 relevance. One could speculate that the conserved features of these channels reflect their common  
27  
28 function (rapid release of osmolytes in response to membrane tension) while their characteristic  
29  
30 differences reflect the specific natures of their ecological niches <sup>55</sup>. Additional examples may help to  
31  
32 determine the functional range of properties that have been selected by evolution.  
33  
34  
35

### 36 **V. Topological Diversity in the MscS Superfamily**

37  
38 The increased topological complexity of MscS family members (as described above and illustrated in  
39  
40 Figure 4) has been taken to imply regulatory complexity <sup>21, 100</sup>, and data is accumulating that suggest this  
41  
42 may indeed be the case. Many members of the MscS family contain N- and C-terminal domains  
43  
44 dramatically larger than that of MscS, presenting the possibility of additional functions and regulation  
45  
46 sites. For example, the unusually large periplasmic N-terminal region of MscK could regulate channel  
47  
48 activity by preventing gating in the absence of high K<sup>+</sup> <sup>109, 140</sup>. Removal of the N-terminal region of MscK,  
49  
50 including TM helices 1-9, abolishes K<sup>+</sup>-dependent gating and promotes its ability to provide protection  
51  
52 from hypoosmotic shock <sup>71</sup>. Similarly, the presence of an extra TM helix C-terminal to the pore-forming  
53  
54 helix is unique to MscCG, and can confer the ability to facilitate glutamate efflux when fused to EcMscS  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 <sup>118</sup>. Proteins comprising the bCNG family all encode a large soluble C-terminal domain containing a  
5  
6 cyclic nucleotide-binding domain. This domain has been shown to negatively regulate the  
7  
8 mechanosensitive channel activity of one of the family members <sup>106, 141</sup>.  
9

10  
11 The eukaryotic family members show topology that is just as diverse. A variety of physiological  
12  
13 functions have been attributed to the chloroplast channels MSL2 and MSL3, which contain a C-terminal  
14  
15 cytoplasmic domain three times the size of the MscS soluble domain <sup>125, 142</sup>. Although the regulatory and  
16  
17 functional importance of this domain has yet to be confirmed, preliminary evidence suggests that a highly  
18  
19 conserved domain within this region is required for proper subcellular localization and channel function  
20  
21 *in vivo* (E. S. Haswell, unpublished). Class II (plasma membrane- and ER-localized) eukaryotic homologs  
22  
23 of MscS, such as MSL10, typically share a common topology of 6 TM regions, large soluble N- and C-  
24  
25 termini, and a large cytoplasmic loop between TM helix 4 and 5 <sup>98, 105</sup>, suggesting that their conserved  
26  
27 structure serves a eukaryote-specific function. The large cytoplasmic regions of many Class II proteins  
28  
29 suggest a number of possible regulatory mechanisms. For example, Mys1 and Mys2 contain an EF-hand  
30  
31 Ca<sup>2+</sup>-binding motif <sup>143</sup> in the large cytoplasmic loop between TM4 and TM5. Genetic analyses suggest  
32  
33 that this region is important for sensing and/or controlling Ca<sup>2+</sup> influx as well as contributing to channel  
34  
35 function in response to hypoosmotic stress <sup>105</sup>.  
36  
37  
38  
39  
40  
41  
42

### 43 **FUTURE DIRECTIONS**

44  
45 As we hope we have demonstrated above, these are exciting times for scientists who study  
46  
47 mechanosensitive ion channels. Every new detail regarding the structure, the physiological function, and  
48  
49 the biophysical parameters that govern the gating mechanism of *EcMscS* adds to our understanding of *E.*  
50  
51 *coli* biology, and helps elaborate an important model system for the study of mechanosensitivity.  
52  
53 Prokaryotic homologs of MscS provide additional examples of the ways in which various bacteria might  
54  
55 exploit the membrane tension sensor and osmotic safety valve provided by a MscS family member. The  
56  
57  
58  
59  
60

1  
2  
3  
4 suggestion that more diverged MscS families may have additional regulatory mechanisms overlaid onto a  
5  
6 conserved mechanosensitive channel core is particularly interesting in this regard <sup>106</sup>. The coming years  
7  
8 should also bring a greater understanding of the role played by the diverse eukaryotic family of MscS  
9  
10 homologs. Eukaryotic cells respond to osmotic stress differently than bacteria, inducing cell signaling  
11  
12 pathways in addition to releasing osmolytes <sup>19</sup> Studies of the yeast Msy1 and Msy2 suggest that they  
13  
14 might play a role in both of these responses <sup>105</sup>; further investigation will establish this point. New  
15  
16 discoveries are also likely as some of the technical challenges associated with the study of  
17  
18 mechanosensitive channels are overcome. Approaches to investigate osmoregulation and osmotic stress  
19  
20 response in single cells and organelles may reveal more subtle phenotypes than can be detected in a  
21  
22 bacterial culture or from a whole-plant phenotype. The development of fluorescent biosensors that report  
23  
24 on ion flux, pH, transmembrane voltage, and membrane tension could produce unexpected insights into  
25  
26 the function of MscS-Like mechanosensitive channels in their endogenous cellular context.  
27  
28  
29  
30  
31  
32  
33

### 34 ACKNOWLEDGEMENTS

35  
36 Our current work on MscS-Like channels in plants and microbes is supported by grants from the  
37  
38 National Science Foundation (MCB-1253103) and the National Institutes of Health (R01 GM084211-01).  
39  
40 We gratefully acknowledge the discoveries and insights of our colleagues and apologize to those whose  
41  
42 work we could not include due to size limits.  
43

## TABLES

Table 1. Single-channel properties of MscS family members.

Organism	Gene Name	Amino Acids	Physiological Function	Mutant Phenotype	Subcellular Localization	References	
Prokaryotes	<i>Escherichia Coli</i>	<i>YggB (MscS)</i>	286	Release of ions during hypoosmotic shock	<i>mscS mscL</i> mutant exhibits loss of viability during osmotic down-shock; <i>mscS mscK</i> mutant has complete loss of MscS channel activity	Plasma membrane	Levina <i>et al.</i> , 1999
		<i>MscK (KefA)</i>	1120*	Release of ions in high K <sup>+</sup> environments	<i>mscS mscK</i> mutant has complete loss of MscS channel activity	Plasma membrane	Levina <i>et al.</i> , 1999; Mclaggan <i>et al.</i> , 2002
		<i>YbiO</i>	741	Release of osmolytes in high NaCl environments	<i>ybiO</i> mutant has loss of 20 pA channel activity	Plasma membrane	Edwards <i>et al.</i> , 2012
		<i>YjeP</i>	1107	Release of ions during hypoosmotic shock	<i>yjeP</i> mutant has loss of 7.5-13pA channel activity	Plasma membrane	Edwards <i>et al.</i> , 2012
		<i>YnaI</i>	343	NR	<i>ynaI</i> mutant has loss of 2 pA channel activity	Plasma membrane	Edwards <i>et al.</i> , 2012
	<i>Campylobacter jejuni</i>	<i>Cjj0263</i>	627	Osmotic protection and host colonization	<i>cjj0263</i> has decreased viability after osmotic down-shock; <i>cjj0263 cjj1025</i> mutant exhibits impaired chick ceca colonization	Plasma membrane	Kakuda <i>et al.</i> 2012
		<i>Cjj1025</i>	523	Host colonization	<i>cjj0263 cjj1025</i> mutant exhibits impaired chick ceca colonization	Plasma membrane	Kakuda <i>et al.</i> 2012
	<i>Bacillus subtilis</i>	<i>YkuT</i>	267	Osmotic protection	<i>mscL ykuT</i> mutant strain has increased sensitivity to osmotic down-shock	Plasma membrane	Hoffmann <i>et al.</i> , 2008; Wahome and Setlow, 2008; Wahome <i>et al.</i> , 2009
	<i>Corynebacterium glutanicum</i>	<i>MscCG</i>	533	Involved in betaine and glutamate efflux	<i>mscCG</i> mutant is impaired in betaine efflux during hyper and hypoosmotic shock and exhibits a 70% decreases in glutamate export	Plasma membrane	Yao <i>et al.</i> , 2009; Börgen <i>et al.</i> , 2010; Nottebrock <i>et al.</i> , 2003; Nakamura <i>et al.</i> , 2007; Becker <i>et al.</i> , 2013
	<i>Synechocystis sp. PCC 6803</i>	<i>PamA</i>	680	Involved in the transcriptional control of sugar and nitrogen metabolism genes	<i>pamA</i> mutant is glucose sensitive; shows decreased levels of nitrogen-response genes and the stress sigma factor SigE	NR	Osanaï <i>et al.</i> , 2005

Eukaryotes	<i>Arabidopsis thaliana</i>	<i>MSL2</i>	673*	Plastid osmotic stress response; division ring placement	<i>msl2</i> null mutants show defective leaf shape; <i>msl2 msl3</i> mutant has enlarged, round non-green plastids and enlarged chloroplast exhibiting multiple division rings	Plastid envelope	Haswell and Meyerowitz, 2006; Jensen and Haswell, 2011; Wilson <i>et al.</i> , 2011; Veley <i>et al.</i> , 2012	
		<i>MSL3</i>	678*	Plastid osmotic stress response; division ring placement	<i>msl2 msl3</i> mutant has enlarged, round non-green plastids and enlarged chloroplast exhibiting multiple division rings	Plastid envelope	Haswell and Meyerowitz, 2006; Wilson <i>et al.</i> , 2011; Veley <i>et al.</i> , 2012	
		<i>MSL4</i>	881	NR	Loss of predominant MS channel activity in root of the <i>msl4 msl5 msl6 msl9 msl10</i> quintuple mutant	NR	Haswell, Peyronnet <i>et al.</i> , 2008	
		<i>MSL5</i>	881	NR	Refer to <i>MSL4</i>	NR	Haswell, Peyronnet <i>et al.</i> , 2008	
		<i>MSL6</i>	856	NR	Refer to <i>MSL4</i>	NR	Haswell, Peyronnet <i>et al.</i> , 2008	
		<i>MSL9</i>	742	NR	<i>msl9</i> null mutant is associated with a loss of 45 pS activity in root protoplast	Plasma membrane	Haswell, Peyronnet <i>et al.</i> , 2008	
		<i>MSL10</i>	734	NR	<i>msl10</i> null mutant is associated with a loss of 137 pS activity in root protoplast	Plasma membrane	Haswell, Peyronnet <i>et al.</i> , 2008	
		<i>Chlamydomonas reinhardtii</i>	<i>MSC1</i>	522	Chloroplast organization	RNAi-mediated knockdown lines show reduced chlorophyll autofluorescence and loss of chloroplast integrity	Chloroplast envelope	Nakayama <i>et al.</i> , 2007
			<i>Schizosaccharomyces pombe</i>	<i>Mys1</i>	1011	Involved in regulating intracellular Ca <sup>2+</sup> and cell volume during hypoosmotic stress	<i>mys1<sup>-</sup> mys2<sup>-</sup></i> mutants show decreased viability during osmotic down-shock and treatment with CaCl <sub>2</sub>	Perinuclear ER
		<i>Mys2</i>		840	Involved in regulating intracellular Ca <sup>2+</sup> and cell volume during hypoosmotic stress	<i>mys2<sup>-</sup></i> and <i>mys1<sup>-</sup> mys2<sup>-</sup></i> mutants show decreased viability during osmotic down-shock and treatment with CaCl <sub>2</sub>	Cortical ER	Nakayama <i>et al.</i> , 2012

\* = Unprocessed protein

Table 2. Physiological function of MscS family members.

	Species	Name	Unitary conductance	Ion selectivity (P <sub>Cl</sub> : P <sub>K</sub> )	Number of TMHs <sup>c</sup>	Identity in the pore-lining domain + upper vestibule to <i>EcMscS</i> , % <sup>d</sup>	References
Prokaryotes	<i>E. coli</i>	<i>EcMscL</i> <sup>a</sup>	3 nS <sup>1</sup>	Non-selective	2	-	Sukharev, 1994; Häse, 1995
		<i>EcMscS</i>	1.2 nS <sup>1</sup> / 350 pS <sup>5</sup>	1.2 - 3	3	100	Levina, 1999; Sukharev, 2002
		<i>EcMscK</i>	1 nS <sup>1</sup>	< <i>EcMscS</i>	11*	32	Martinac, 1987; Li, 2002
		YjeP	250-400 pS <sup>1</sup>	NR	11*	27	Edwards, 2012
		YbdG <sup>b</sup>	350-400 pS <sup>1</sup>	NR	5*	21	Schumann, 2010
		Ynal	~ 100 pS <sup>1</sup>	NR	5*	30	Edwards, 2012
		YbiO	~ 850 pS <sup>1</sup>	NR	12*	24	Edwards, 2012
	<i>S. pomeroyi</i>	<i>MscSP</i>	1.04 nS <sup>2</sup>	1.4	3*	49	Petrov, 2013
	<i>T. tengcongensis</i>	<i>TtMscS</i>	134 pS <sup>1</sup>	8.7	3	29	Zhang, 2013
	<i>C. glutamicum</i>	<i>MscCG</i>	328 pS <sup>2</sup>	0.3	4	29	Börngen, 2010; Becker, 2012
<i>M. jannashii</i>	<i>MscMJLR</i>	2 nS <sup>3</sup>	0.2	5*	41	Kloda, 2001a, b	
	<i>MscMJ</i>	270 pS <sup>3</sup>	0.16	5*	36	Kloda, 2001a	
Eukaryotes	<i>C. reinhardtii</i>	MSC1	390 pS <sup>4</sup>	7	5*	32	Nakayama, 2007
	<i>A. thaliana</i>	MSL10	103 pS <sup>5</sup>	5.9 (P <sub>Cl</sub> : P <sub>Na</sub> )	6*	18	Haswell, 2008; Maksae, 2012

<sup>1</sup> 200 mM KCl, 90 mM MgCl<sub>2</sub>, 10 mM CaCl<sub>2</sub>, and 5 mM HEPES (pH 7.0)

<sup>2</sup> 250 mM KCl, 90 mM MgCl<sub>2</sub>, and 5 mM HEPES (pH 7.2)

<sup>3</sup> 200 mM KCl, 5 mM MgCl<sub>2</sub>, and 5 mM HEPES (pH 7.2)

<sup>4</sup> 200 mM KCl, 40 mM MgCl<sub>2</sub>, 10 mM CaCl<sub>2</sub>, 0.1 mM EDTA, and 5 mM HEPES-KOH (pH 7.2)

<sup>5</sup> 96 mM NaCl, 2 mM KCl, 2 mM CaCl<sub>2</sub>, 1 mM MgCl<sub>2</sub>, and 5 mM HEPES (pH 7.38)

<sup>6</sup> 100 mM KCl, 10 mM MgCl<sub>2</sub>, 10 mM HEPES-KOH (pH 7.4)

<sup>a</sup> MscL is not a MscS homolog, added for reference

<sup>b</sup> Channel activity was only shown for a V229A mutant of YbdG-encoded protein

<sup>c</sup> number of transmembrane helices were predicted via TMHMM 2.0 server.

<sup>d</sup> Alignments were made using Kalign algorithm in Unipro UGENE software

\* = Predicted

NR = not reported

## FIGURE LEGENDS

**Figure 1. Schematic representation of models for mechanosensitive channel gating.** (A) The intrinsic bilayer model, wherein lateral membrane tension favors the open state of the channel. (B) The

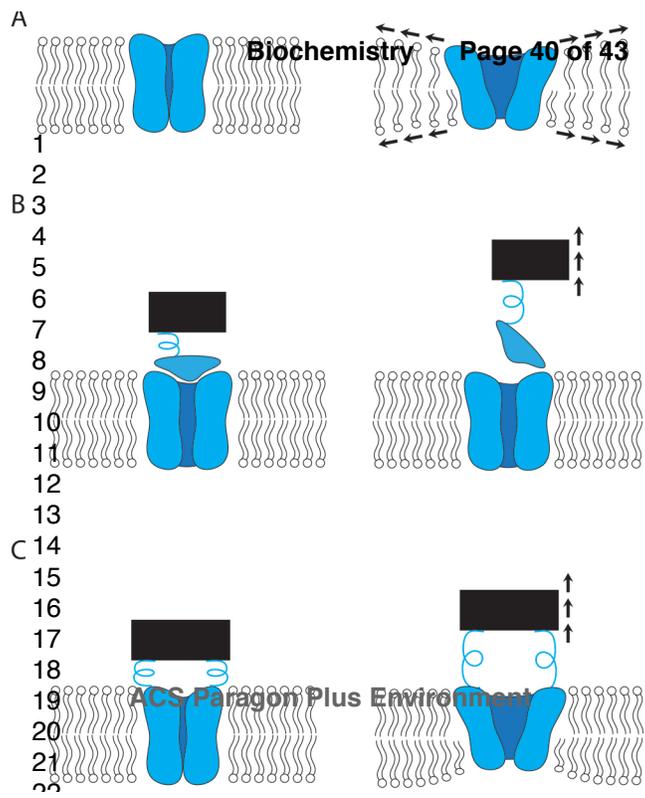

1  
2  
3  
4 tethered trapdoor model, wherein a tether to an extracellular (in this case) component exerts force on the  
5  
6 channel, leading to its gating. (C) The unified model, wherein a tether to an extracellular component leads  
7  
8 to reorientation of the channel within the membrane bilayer, thereby gating it.  
9

10  
11 **Figure 2. Crystal structures of *E. coli* MscS and homologs.** (A) *EcMscS* in “inactive/non-  
12  
13 conductive state” (2OAU, Steinbacher, 2007); (B) *TtMscS* from *T. tengcongensis* in “closed” state  
14  
15 (3UDC, Zhang, 2012); (C) A106V *EcMscS* mutant in “open” state (2VV5, Wang, 2008); (D) *EcMscS* in  
16  
17 “open” state (4HWA, Lai, 2013). The monomers in a heptamer labeled by color; surface map, viewed  
18  
19 from the periplasm is truncated at I175 in order to display unobstructed channel pore. Left panel: side  
20  
21 view of the heptameric channel; middle panel: view of the channel from the periplasmic side; right panel:  
22  
23 space-filling representation of the channel with a pore, view from the periplasmic side. Basic residues are  
24  
25 blue, acidic residues are red, polar residues are green, non-polar residues are white. The images were  
26  
27 generated with VMD software (University of Illinois).  
28  
29  
30

31  
32 **Figure 3. The conserved region of *EcMscS* and *TtMscS* monomers in different conformations.** A  
33  
34 single monomer of (A) *EcMscS* (aa 27-175) in a nonconducting state (2OAU, Steinbacher, 2007); (B)  
35  
36 *TtMscS* (aa 13-175) in a nonconducting state (3UDC, Zhang, 2012); (C) *EcMscS* A106V (aa 25-175) in  
37  
38 an open state (2VV5, Wang, 2008). (D) Superposition of panel A (silver) with a single monomer of  
39  
40 *EcMscS* (27-175) in an open state (4HWA, Lai, 2013, cyan). The kink-forming residues G113 (*EcMscS*)  
41  
42 and G109 (*TtMscS*) are represented as blue spheres and the A106V mutation as a red sphere. The vapor-  
43  
44 lock residues L105 and L109 (*EcMscS*) and L104 and F108 (*TtMscS*) are labeled in yellow. F68 and  
45  
46 L111, residues proposed to mediate the TM2-TM3 interaction in *EcMscS* (Belyy, 2010) are labeled  
47  
48 magenta. Images were generated with VMD software (University of Illinois).  
49  
50  
51

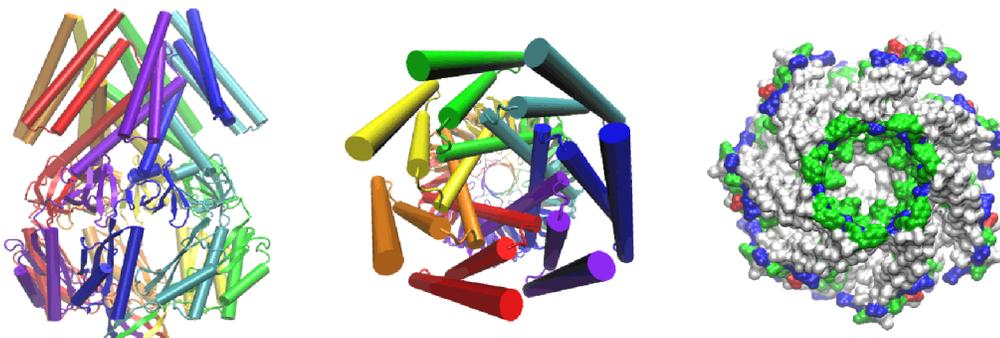

52  
53 **Figure 4. Monomer topologies of representative MscS family members.** MscS monomer topology  
54  
55 was rendered based on Naismith, 2012. For the purpose of clarity TM3b of MscS is represented outside  
56  
57 the lipid bilayer. MscK and MscCG topologies were predicted with TOPCONS (<http://topcons.net/>) and  
58  
59
