ABSTRACT OF THE THESIS

Performance and Emissions Study of N+3 and N+4 Engine Model with Several Fuel types Using

NPSS

by

Abel Solomon

Master of Science in Mechanical Engineering Washington University in St. Louis, 2023

Professor Ramesh Agarwal, Chair

The aviation industry is known to be one of the major contributors to greenhouse gases accounting for 4.9% of the global greenhouse emissions. With the ever-increasing threat of climate change to the overall survival of the planet, the exploration of new technologies and alternative energy sources that minimize greenhouse gas emissions are of paramount importance. In this regard, the development of propulsion systems well suited for performance and emissions requirements of future commercial aircrafts plays a crucial role. This thesis investigates N+3 and N+4 technology level propulsion systems that are proposed by NASA as a possible propulsion system for an advanced single-aisle commercial aircraft. Numerical simulation is utilized to evaluate the performance and emissions associated with the engines. The simulation is performed on the software called NPSS which is a component based object-oriented engine cycle analysis and simulation tool. Liquid hydrogen (LH2), liquefied natural gas (LNG), ammonia (NH3), and ammonia-borane (AB) are explored as alternative fuel sources alternative to the conventional Jet-A fuel.

The engine size is fixed using published reference data from NASA and a fixed core engine model is developed and validated against the results obtained from fundamental propulsion equations coded in MATLAB; good agreement is obtained (with in $\pm 8\%$) for variation in Thrust Specific Fuel Consumption (TSFC) with Bypass Ratio (BPR). After validation of the NPSS engine model, a BPR sensitivity study is performed and the result shows that there is a significant improvement in TSFC with increasing BPR. To reduce the effect of the undesirable consequence of increasing drag with BPR, it is crucial to find the optimal BPR level and The BPR sensitivity study presented in this thesis can be used as a starting point in sizing an engine during design process. Although the emissions study presented in this paper uses indexes, having robust models that can accurately predict emissions associated with alternative fuels is essential for the acceleration of technology development and implementation. In the absence of experimental data, the results presented in this work can be used as a reference for future attempts to enhance the accuracy of the emissions estimation.

Chapter 1: Motivation and Introduction

This chapter presents the motivation behind the research presented in this thesis. A brief introduction to Numerical Propulsion System Simulation (NPSS) software is given. Basic working principles of the N+3 and N+4 technology level turbofan engines are discussed. Lastly, the scope of the thesis is presented as it appears in the consecutive chapters.

1.1 Motivation

The effect of global warming and its associated impact on climate change necessitate the urgent need for multi-faceted solutions for the planet to be saved from disastrous consequences. The main contributors to global warming are the release of greenhouse gases such as carbon dioxide (CO_2), methane (CH_4), water vapor (H_2O) and other particulates into the atmosphere through the burning of fossil fuels [1]. In comparison to other greenhouse gases, CO_2 emission is by far the largest contributor to the global warming accounting for 76% of the global greenhouse gas emissions [2]. The global aviation industry alone contributes about 2.1% of the global CO_2 emissions, and when included with other greenhouse gases, it accounts for 4.9% making it a significant contributor to global warming [3]. Therefore, the need for a cleaner fuel energy source for aviation to achieve a zero-emission future is apparent.

In recent years, the aviation industry therefore is increasingly focused on exploring alternative energy sources (fuels) that can reduce the environmental impact of its current carbon emissions due to combustion of Jet-A fuel [4]. One way to accomplish this goal is to explore propulsion technologies that support alternative fuels which have reduced or zero-carbon emissions such as hydrogen or ammonia among others. For regional travel distances of 1000

nautical miles or less, the current advancement in battery and fuel cell technology have made it possible to create propulsion systems with zero emissions assuming that the fuel used for fuelcell (namely the hydrogen) is obtained from sustainable sources such as solar, wind, or nuclear energy [5]. However, the application of such technologies is limited to short-haul flights; the gas turbine combustion remains the only viable option for long distance air transportation of greater than 1000 nautical miles which covers about 70% of the world air traffic. In this regard, sustainable aviation fuels (SAFs) and non-hydrocarbon fuels such as liquid hydrogen (LH2), Ammonia (NH₃), and Ammonia Borane (AB) are promising alternatives to the Jet-A fuel currently in use. This study aims to evaluate the performance of these alternative fuels by conducting numerical investigation of propulsion and associated emissions using NPSS. The engine models explored in this numerical investigation are N+3 and N+4 technology level high bypass geared turbofan engines.

1.2 Introduction

1.2.1 N+3 and N+4 Technology Level Turbofan Engines

To achieve the ambitious goals of the emission free next generation of aircrafts, development of new propulsion systems is imperative. N+3 and N+4 technology level turbofan engines are advanced propulsion systems that are being developed by the aerospace industry to meet the growing demand for more efficient and environmentally friendly aircrafts while advancing in operational capability [6, 7]. The terms N+3 and N+4 refer to the third and the fourth generation of engine technologies, respectively. In addition to improving the overall engine performance and reliability, this new generation of propulsion systems are expected to reduce fuel consumption by about 30%, reduce carbon emission by about 70%, and reduce noise by about 65% compared to current technology levels. The advancement of new technologies

such as N+3 and N+4 propulsion systems are of paramount importance in the development of aircrafts that are environmentally friendly, efficient, and cost effective.

1.2.2 Numerical Propulsion System Simulation (NPSS)

Numerical Propulsion System Simulation (NPSS) is a component based object-oriented engine cycle analysis and simulation tool. It was originally developed by NASA Glenn Research Center to be used for the creation, study and sharing of complete aerothermal-mechanical computer simulations of propulsion systems [8]. In NPSS, the model definitions are given through input files. The software has a set of modules that correspond to the different components of a gas turbine engine such as fan, compressor, burner, turbine, and nozzles. A complete engine model can be created by combining the individual modules. The simulation system also has a built-in NIST compliant gas property packages to perform different thermochemistry simulations. NPSS has sophisticated solver with auto-setup, constraints, and discontinuity handling. The object-oriented design of NPSS facilitates user-definable elements, functions, and models. There are several published engine cycle data sets on NASA's website, including N+3 and N+4 engine cycle data [6, 7], which can be utilized to model an engine in NPSS.

1.3 Scope of Thesis

The goal of this research is to explore alternative fuel sources that are capable of supplying the required power level while minimizing emissions. The alternative fuels considered are LH₂, NH₃, AB, and LNG. Numerical simulation is utilized to quantify emissions and propulsive efficiencies of both N+3 and N+4 technology level propulsion systems. The simulation is executed using NPSS.

Chapter 2: Choice of Alternative Fuels: In this chapter, the alternative fuels investigated in this thesis are presented. The reasoning behind the choice of alternative fuels is discussed.

Chapter 3: NPSS Code Development for N+3 and N+4 Engine Designs: This chapter explains the development and validation procedures of the NPSS code for the N+3 and N+4 representative engine models. The engines design parameter as well as equations used for performance evaluation are discussed in detail.

Chapter 4: Validation of NPSS: In this chapter, the validation of the NPSS code against results from a MATLAB code is discussed. The main aim of this chapter is to investigate the capability of NPSS to model and size a rubber engine and produce expected results from rudimentary propulsive performance calculations.

Chapter 5: Performance Study of N+3 Turbofan Engine Model with Several Types of Fuels Using NPSS: In this chapter, the performance of a fixed core propulsive system representative of N+3 engine model is evaluated. A bypass ratio (BPR) sensitivity study on the engine, quantified by the thrust specific fuel consumption (TSFC), is discussed and the significance of the results is presented.

Chapter 6: Emission studies of N+3 and N+4 Technology Level Propulsion Systems with Alternative Fuels: A detailed description of the emissions calculation method and performance comparisons among Jet-A, liquefied natural gas (LNG), liquid hydrogen (LH₂), ammonia (NH₃), and ammonia-borane (AB) are presented in this chapter. General cruise cycle data is presented to aid in further research efforts of aircraft and propulsion system designs that take emissions into account. **Chapter 7: Summary:** This chapter summarizes the main findings of the research. Recommendations based on the findings and future directions are discussed briefly.

Chapter 2: Choice of Alternative Fuels

Conventional Jet-A fuel is the commonly used energy source for both commercial and military aircrafts. It is a kerosene-based aviation fuel with enhanced qualities of low freezing point and high flash point which makes it ideal for use in aviation [1]. Although Jet-A meets the current safety, performance, and environmental regulations, it is not suitable for future generations of aircrafts that would have to meet much more strict environmental regulations and performance requirements. Since Jet-A is kerosene-based fuel it is in fact a fossil fuel and has a negative impact on the environment including greenhouse gas emissions. At the moment, Jet-A is the standard aviation fuel every airport supplies, thus the explorations of alternative fuel sources to the conventional Jet-A fuel should be the first steep to reduce the environmental impact of air transport. The alternative fuels explored in this research are liquid hydrogen (LH₂), liquid natural gas (LNG), ammonia (NH₃), and ammonia borane (BH₃NH₃ or AB). The advantages and disadvantages of each fuel are discussed below.

2.1 Liquid Hydrogen (LH₂)

Liquid hydrogen is a promising candidate for aviation fuel due to its high energy content per unit of mass. The lower heating value (LHV) of liquid hydrogen is about 51,590 BTU/lbm which is significantly higher than the LHV value of conventional Jet-A fuel which is around 18,500 BTU/lbm. However, there are downsides associated with the use of liquid hydrogen, primarily in storage, transportation, and volume requirements. Due to the extremely low boiling point of hydrogen (-252.9°C), it must be stored in a cryogenic tank at a very high pressure to keep it in liquid form, and this requires significant amount of energy. Moreover, since liquid hydrogen has very low density, the fuel tank volume requirement is considerably higher than that of conventional Jet-A fuel. Although the stoichiometric equation for LH_2 combustion reaction (with air) shown in Eq.1 produces only N₂ and H₂O as byproducts [2], at elevated temperatures the combustion can result in the production of NO_x which is the primary contributor to acid rain [3].

$$2H_2 + 7.546N_2 + 0_2 \rightarrow 3.774N_2 + 2H_20 \tag{1}$$

2.2 Ammonia (NH₃)

The use of ammonia as an aviation fuel has gained interest in recent years due to its low greenhouse gas emission with only NO_x as the product of its combustion. In addition, the production of ammonia can be carbon-neutral or even carbon-negative depending on how it is sourced and the energy used to produce it. It can be produced easily from biomass using renewable energy sources. The storage and transportation of ammonia is rudimentary and does not require much energy as compared to liquid hydrogen. However, it has a very low LHV value of 7,996 BTU/lbm which implies a larger fuel tank, just as in the case of liquid hydrogen, and more fuel mass is required. Despite these challenges, ammonia has the potential to be used as an environmentally friendly aviation fuel. Equation 2 shows the stoichiometric combustion reaction of ammonia with air [4]. The formation of NO_x is seen at elevated temperature combustion.

$$2NH_3 + 5.64N_2 + 1.5O_2 \rightarrow 6.64N_2 + 3H_2O$$
(2)

2.3 Ammonia Cracking (NH₃)

Instead of using ammonia as an aviation fuel directly, it can be cracked catalytically or via a plasma reactor to extract the hydrogen [5]. Essentially, ammonia is considered to be a hydrogen carrier in this application. The high density (~0.6 kg/L) and high hydrogen content by mass (~17.65 %) of ammonia makes possible to store more hydrogen per volume of fuel as

compared to pure liquid hydrogen [6]. The drawback of ammonia cracking is the needed for complicated auxiliary units required for cracking ammonia on board and the associated extra energy cost. For the purpose of this study, hydrogen is assumed to be cracked off of ammonia, whether it is catalytically or via a plasma reactor, prior to being injected into the combustion chamber. Thus, hydrogen is assumed as a fuel for combustion; however, the LHV value is adjusted by considering the density of ammonia [7].

2.4 Ammonia Borane (BH₃NH₃ or AB)

Ammonia borane is another alternative fuel for use as a hydrogen carrier to overcome the problematic and expensive requirements of hydrogen storage and transportation. It has higher hydrogen content by mass releasing about 19.6 wt.% of hydrogen as can be seen in Eq. 3 [8]. Ammonia Borane is solid at standard room temperature and pressure and although the decomposition of hydrogen is possible at solid-state, it cannot be used as a fuel for aircraft engines as they require liquid fuels. Also, combusting ammonia borane at the turbine inlet temperature of a representative turbofan engine can lead to crystalline products creating issues for turbine life and performance. Thus, just as in the case of ammonia cracking, the dehydrogenation of ammonia borane can be induced via catalysts or through thermal decomposition to produced injectable hydrogen. The thermal decomposition of Ammonia and Ammonia Borane occurs at temperatures much cooler than in a typical turbine engine combustor as shown in Table 1 which make this a potential option [4, 7].

$$BH_3NH_3 \to BN + 3H_2 \tag{3}$$

Table 1: H₂ release temperature points during thermal decomposition of NH₃ and BH₃NH₃.

Thermal	Ammonia	Ammonia Borane
Decomposition	NH3 [R]	BH3NH3 [R]

Temps		
1 st H ₂	2471.7	689.7
2 nd H ₂	NA	725.7
3 rd H ₂	NA	2651.7

2.5 Liquefied Natural Gas (LNG)

LNG is advertised as the "cleanest fossil fuel" because it is primarily made up of methane (CH₄). The combustion of LNG produces less soot and generates 30% less carbon dioxide than oil fuel and a 50% decrease in NOx production [9]. In addition, LNG has LHV of around 21,000 BTU/lbm [10] which is higher than that of Jet-A fuel. The stoichiometric reaction for the combustion of LNG in air is given by Eq. (4) [11]. For the purpose of this study, since greater than 90% of LNG is methane, methane is used as a fuel when modeling the propulsion in NPSS with the LHV value of LNG.

$$CH_4 + 2O_2 + 7.53N_2 \rightarrow CO_2 + H_2O + 7.53N_2$$
(4)

Table 2 summarizes the energy content of the fuels used in this research. Note that the LHV values for NH₃ cracking and BH₃NH₃ thermal decomposition reflect the LHV value of hydrogen adjusted with its wt.% in each fuel.

Table 2: Properties associated with Jet-A, liquefied natural gas (LNG), liquid hydrogen (LH₂), ammonia (NH₃), ammonia cracking, and thermal decomposition of Ammonia borane (AB).

<u>Chapter 3: NPSS Code Development for N+3</u> <u>and N+4 Engines</u>

3.1 NPSS Development

Turbofan engines can achieve higher thrust level with lower fuel consumption compared to turbojet engines by utilizing some of the energy produced by the turbine to drive a fan. The fan draws large amount of air into the engine and thus yields higher thrust per unit amount of fuel used. One can increase the size of the fan to get lower Thrust Specific Fuel Consumption (TSFC) value. However, increasing the size of fan creates aerodynamic issues since the drag force would increase. Hence, modern turbofan engines are designed to achieve lower TSFC values while keeping the aerodynamic drag created by a larger fan as low as possible.

The next generation of propulsion systems is designed to eliminate some of the drawbacks of the current turbofan engines such as noise, fuel efficiency, and most importantly emissions. N+3 and N+4 propulsion systems have been proposed to do just that. Table 3 shows the performance parameters for N+3 and N+4 engines as published by NASA [1, 2]. The current turbofan engines in use are not suited for use with the various alternative fuels discussed in chapter 2. N+3 and N+4 propulsion systems are expected to introduce new engine architectures that are capable of running on these new fuels.

Table 3: Performance parameters for NASA N+3 and N+4 high bypass geared turbofan engine models

Figure 1 shows representative schematics of the N+3 and N+4 models proposed by NASA. The major components of N+3 and N+4 turbofan engine models include a fan, a low-pressure compressor (LPC), a high-pressure compressor (HPC), a high-pressure turbine (HPT), and a low-pressure turbine (LPT). The addition of an extra compressor enhances the amount of thrust that can be extracted by burning the same amount of fuel while the added turbine supplies the necessary energy needed to turn the fan and compressor blades.

Figure 1: Schematic of a double a double spool geared turbofan engine representative of the NASA N+3 and N+4 engine models.

Numerical Propulsions Systems Simulation (NPSS) software is employed to study the performance and associated emissions of N+3 and N+4 technology level turbofan engines. NPSS is an advanced, object-oriented code written in C++ that is widely used in the industry for modeling thermodynamic propulsion cycles [3]. The code acts as a flow network solver that can simulate all environmental conditions and modes of flight to study the performance of an engine model. In that regard, the N+3 generation high bypass geared turbofan engine cycle was modeled in NPSS based on published NASA engine cycle data [4]. The publicly available published data from NASA include the engine architecture, turbomachinery maps, and technology level material temperatures which were retrieved from NASA's OpenMDAO GitHub repository [1, 5, 6]. As demonstrated by previous studies, NPSS has the capability to simulate propulsion system developed using engine cycle models based on specific performance parameters and publicly available data [4, 7]. The NASA N+3 high bypass technology reference includes several improvements to the architecture based on assumed technology advancements and compressor loading capability. These improvements include a lower fan pressure ratio (1.3), a higher overall

pressure ratio (55), a higher burner outlet temperature (3400°R), and a larger bypass ratio (24) compared to the standard reference CFM 56 [1].

The first step in this study was the development and validation against published performance data of a representative N+3 engine model created using the publicly available engine parameters. To study the performance and emissions of various alternative fuels for N+4 technology level engine, the same model was updated with NASA N+4 performance parameters from Ref. [2]. The NASA N+4 engine report considers multiple advancement options for the propulsion system including designs for Liquefied Natural Gas (LNG), an un-ducted fan (UDF) propulsor, solid oxide fuel cell power plant with UDF, and aft-fuselage mounted ducted turbofans for boundary layer ingestion and wake propulsion [2]. For the purpose of this study, only the original ducted gFan++ Advanced Turbofan propulsion system level requirements were modeled in NPSS. The reference report [2] details the thrust, the thrust specific fuel consumption (TSFC), the compressor and turbine stage numbers, and the compressor pressure ratio values. However, other parameters such as the high-pressure compressor exit pressure and temperature and the high-pressure turbine inlet pressure and temperature are not given. Thus, when modeling the N+4 technology level turbofan engine all the missing information was substituted with N+3 assumptions.

3.2 Propulsion System Equations

The performance of the representative N+3 and N+4 engine models at a single design point can be calculated using basic propulsion equations. According to [8] the thrust force that pushes an aircraft powered by a turbofan engine forward is a result of the flow of air through the fan and the core. As can be seen from Eq. (1), the net thrust is a combination of the thrust produced by the fan and the thrust produced by the engine core.

Net Thrust = Thrust of Fan + Thrust of Core (1)

$$T = (\dot{m}_f v_f - \dot{m}_f v_o) + (\dot{m}_e v_e - \dot{m}_c v_o)$$

where *T* is thrust in [lbf], \dot{m}_f , \dot{m}_e , and \dot{m}_c are the mass flow rates at the fan exhaust (connected to the bypass bleed), the core exhaust, and the core inlet, respectively in [lbm/s], v_f , v_o , v_e , are the velocities at the fan exhaust (going to the bypass bleed), the fan entrance (free stream velocity), and the core exhaust, respectively in [ft./s]. The total mass flow of the air is the sum of the mass flow going through the bypass bleed and the mass flow going through the core as can be seen in Eq. (2) below:

$$\dot{m}_o = \dot{m}_f + \dot{m}_c \tag{2}$$

where \dot{m}_o represent the total mass flow of air entering the engine in [lbm/s]. The thrust can be adjusted by changing the size of the core and the bleed. Moreover, the ratio between the fan exhaust mass flow rate to the compressor mass flow rate gives the bypass ratio as given in Eq. (3).

$$BPR = \dot{m}_f / \dot{m}_c \tag{3}$$

Equation (1) can thus be written in terms of *BPR* and \dot{m}_o as shown in Eq. (4):

$$T = (\dot{m}_e v_e - \dot{m}_o v_o) + BPR * \dot{m}_c * v_f \tag{4}$$

The net thrust (T_{net}) can also be expressed in terms of the change in velocity between the free stream and the jet (ΔV) as:

where
$$T_{net} = \dot{m}\Delta V \tag{5}$$

$$\Delta V = V_{jet} - V_o$$

$$V_{jet} = M_9 * \alpha$$

The \dot{m} in Eq. (5) represents the change in mass of the aircraft overtime. M_9 is the core nozzle exit Mach number and α is the speed of sound calculated using Eq. (6) as:

$$\alpha = \sqrt{\gamma RT} \tag{6}$$

where γ is the adiabatic index (~1.4 for diatomic molecules such as air), *R* is the universal gas constant (~53.4 ft·lbf/lb·°R for air), and *T* is the absolute temperature of the air in which the aircraft is flying through. The change in the kinetic energy of the aircraft can be calculated by Eq. (7):

$$\Delta KE = \frac{1}{2}\dot{m}V_{jet}^2 - \frac{1}{2}\dot{m}V_o^2 = \frac{1}{2}\dot{m}\Delta V(2V_o + \Delta V)$$
(7)

For a fixed free stream velocity V_o , propulsive efficiency and V_{jet} have an inverse relationship as shown in Eq. (8):

$$\eta_{prop} = \frac{TV_o}{\Delta KE} = \frac{2V_o}{(V_o + V_{jet})} \tag{8}$$

Moreover, the *FPR*, which is the ratio of the fan exit pressure to fan inlet pressure, can be calculated using the nozzle exit Mach number as given in Eq. (9). For the case of an ideal engine, the nozzle exit pressure matches the ambient pressure ($P_{\infty} = P_1 = P_9$).

$$FPR = \frac{P_2}{P_1} = \frac{P_2}{P_{\infty}} = \left[1 + \frac{\gamma - 1}{2}M_9^2\right]^{\frac{\gamma}{\gamma - 1}}$$
(9)

By solving Eq. (9) for M_9 , the nozzle exit Mach number can be expressed in terms of the *FPR* and the fan inlet pressure (P_1) as given in Eq. (10).

$$M_{9} = \sqrt{\frac{2(\frac{\gamma}{\gamma-1}\sqrt{FPR}-1)}{\gamma-1}}$$
(10)

Thus, as *FPR* is increased to a point in an ideal engine, the nozzle exit Mach number M_9 , and consecutively V_{jet} increases. This increase in V_{jet} brings about a decrease in the propulsive efficiency as the two are inversely related. The focus of this thesis is to study the performance of the N+3 and N+4 turbofan engine model while altering the *FPR*.

<u>Chapter 4: Study of the Effect of Bypass</u> <u>Ratio on Thrust Specific Fuel Consumption</u>

4.1 Introduction

NPSS is utilized to study the effect of *BPR* on TSFC and the NPSS results are validated against simulation results obtained using MATLAB. Thrust Specific Fuel Consumption (TSFC) represents the amount of fuel used per unit thrust; lower value of TSFC indicates less fuel is being used to achieve the required thrust level. Thus, modern turbofan engines are designed to have lower TSFC values as it increases the overall efficiency of the engine and decreases fuel consumption. It is a well-known fact that the TSFC is affected by how much air is let into the turbofan engine. Fan Pressure Ratio (*FPR*) represents the ratio of the fan exit pressure to inlet pressure, and the amount of air being sucked into the engine can be controlled by changing this pressure ratio. As *FPR* is increased in an ideal engine, the nozzle exit Mach number and consequently the jet velocity (V_{jet}) increases. This increase in V_{jet} brings about a decrease in the propulsive efficiency as the two are inversely related. The focus of the work presented in this chapter is to study the performance of the N+3 turbofan engine model while altering the *FPR*.

4.2 Method

For validation of the NPSS model, a MATLAB code from [1] is utilized to study performance of a representative N+3 engine. The flight conditions such as free stream velocity and altitude are set at the start in the code. The necessary propulsive equations discussed in chapter 3 are then used for calculating the performance of different components of the engine. Two different methods are used in the performance calculations: a fixed core method with constant core mass flow rate and fuel flow rate and thrust convergence method with constant thrust level. In both methods the *BPR* is varied to observe the change in thrust and fuel flow.

The NPSS model contains all the elements and connections that are representative of an N+3 propulsion system. The results of the simulation are defined using viewers that extract data from the system. Moreover, user defined functions, input files, and performance maps of the different engine components are included in the simulation. Both conventional Jet-A fuel and LH₂ fuel are used to evaluate the performance of the engine. It should be noted that there are major design differences between the MATLAB simulation and the NPSS simulation. One of these major design differences is the fact that the NPSS model has multistage compressors and turbines that are defined by detailed maps of the representative N+3 technology. In the MATLAB, the engine is composed of a single stage compressor and turbine that uses simple temperature and pressure calculations with assumed constants. The NPSS model takes predefined dependent variables such as Fnet, Tt4, and OPR and solves for the performance of the engine through the independent variables such as fuel flow, *LPC PR*, and *BPR*. The complete list of the solver dependent and independent variables is given in Fig. 2.

Solver Dependent Variables ** "GearBox.integ_shaftTheta", ShH.integrate_Nmech", ShL.integrate_Nmech" ShFan.integrate Nmech", dep Fnet", dep F040Tt" dep Des OPR" } * Solver Independent Variables ** "HPT.S_map.ind_PRbase", LPT.S_map.ind_PRbase", GearBox.ind_theta", ShFan.ind Nmech", ind Wfuel", ind_LPC PR" ind SpltBPR" }

Figure 2: Screenshot of the command prompt window showing NPSS Solver's dependent and independent variables.

Similar flight conditions are used in both the NPSS and MATLAB models. But since the MATLAB engine design is different from the NPSS engine design, the aim of this study is to show the overall trend of the engine performance by varying *BPR* using NPSS and MATLAB and not to dwell on the quantitative comparison. The NPSS simulation is first performed with the Fnet, Tt4, and OPR set to 6126.7 lbf, 3150.0°F, and 55, respectively. A total of seven simulations with *FPR* values of 1.276, 1.3, 1.32, 1.34, 1.36, 1.38, and 1.4 are conducted and the performance data of the engine is recorded at each *FPR* value. As the OPR is fixed in the NPSS engine model, an increase in the *FPR* is mitigated by a decrease in the *BPR*. The performance data obtained from NPSS is then used to replicate the same flight conditions in MATLAB. Thus, the *FPR*, the core mass flow (m_c), and the *BPR* values of the MATLAB code are all changed to match the values obtained using NPSS. TSFC values corresponding to the each *BPR* are obtained from MATLAB. These values are later used to generate plots that show the relationship between TSFC and *FPR* with *BPR*.

4.3 Results

Figure 3 shows some examples of the viewOut file obtained from NPSS. The viewOut file contains the performance data of the engine. Some important parameters are highlighted in yellow.

b) viewOut file for FPR = 1.34 (Jet A Fuel)

Figure 3: Sample screenshots of the viewOut file obtained from NPPS

As can be seen in Fig. 3, the OPR, Fnet, and HPC PR stay the same even though *FPR* is changing. Moreover, LPC PR, HPT, and LPT changed with *FPR* while their efficiency stayed the same. The other important thing to notice here is that both the core mass flow (represented by SplitFan.F1_01) and the bypass bleed (represented by Splintfan.F1_02) change with *FPR*. However, the two values change with *FPR* in opposite direction, core mass flow in the increasing direction and bypass bleed in the decreasing direction. This leads to an overall decrease in the *BPR* as *BPR* is the ratio of the bypass bleed to the core mass flow.

Figures 4 and 5 show how the TSFC and *BPR* were affected by the change in *FPR* for Jet-A fuel and for LH₂, respectively. As can be seen in the plots, TSFC increased with increasing *FPR* while *BPR* decreased with increasing *FPR* for both fuel types. Higher TSFC value means more fuel is being consumed to achieve the necessary thrust level. Moreover, the observed

increasing trend of the TSFC value is a direct effect of the decrease in the *BPR* value. The *BPR* showed a decreasing trend with an increase in *FPR*. This was because the OPR was kept constant and thus, an increase in *FPR* was mitigated by a decrease in *BPR* to match up the OPR value of 55.

Figure 4: TSFC vs. FPR (primary axis) and BPR vs. FPR (secondary axis) for Jet-A fuel. The linear fit is placed to show the increasing or decreasing trend of the plot. The plots can be fitted well using a polynomial fit of degree 3 (see Appendix A for detail).

Figure 5: TSFC vs. FPR (primary axis) and BPR vs. FPR (secondary axis) for LH_2 fuel. The linear fit is placed to show the increasing or decreasing trend of the plot. The plots can be fitted well using a polynomial fit of degree 3 (see Appendix A for detail).

Comparing plots in Fig. 4 and Fig. 5, one can see that the TSFC value when using LH₂ fuel is much lower than the TSFC value when using conventional Jet-A fuel. This indicates less amount of fuel (by mass) is needed to reach the required thrust level. This has a direct effect in decreasing both emission and cost of flights as less fuel is being consumed. The above study has been carried out to demonstrate how the engine is being sized in NPSS. The data points from Fig. 4 were then used in the MATLAB code obtained from the appendix of Ref. [1]. (See Appendix A for the modified version of the MATLAB code).

Figure 6 shows the decreasing trend of TSFC with increasing *BPR* of both NPSS and MATLAB simulations run using Jet-A fuel. The plot shows a decrease in TSFC value with an

increase in *BPR*. Even though the flight conditions in NPSS were replicated in MATLAB as much as possible, the difference in the engine designs produces discrepancies. As can be seen in this plot, the NPSS simulation result shows a steep decrease in TSFC with increase in *BPR* compared to the MATLAB simulation results.

Figure 6: Plot showing the effect of increasing BPR on TSFC using Jet-A as a fuel source.

The steep decrease in TSFC value for NPSS came from the core and bypass bleed design used in the engine model. The NPSS model was set to have a rubber engine, with both the core and the bypass being able to change size each time design iteration is run. An increase in *FPR* brought about an increase in the core mass flow and a decrease in the bypass bleed, thus a decrease in *BPR*. The NPSS model has a double edge sword effect as both the core and the bypass are changing size. In the MATLAB code, however, the core mass flow is kept constant, thus an increase in *BPR* is achieved through an increase in the bypass bleed only. For this reason, the change in TSFC value is much lower when using the MATLAB simulation compared to when using the NPSS simulation. It is possible to replicate the constant core flow in NPSS and allow only the bypass flow to change, but this would require a completely new set-up for NPSS solver. The fixed core mass flow solver setup is explored in chapter 5.

4.4 Conclusion

Lower TSFC values are desirable in the aviation industry as lower TSFC value would mean less fuel is being used to reach the required thrust. Thus, commercial airlines can cut their fuel cost by mounting an engine with lower TSFC value. However, there is a tradeoff as lower TSFC values are achieved by bigger engines. Hence, both aerodynamic and engine size need to be considered to optimize the fuel consumption of an airplane.

The decrease in TSFC and thus the fuel consumption is beneficial not only financially, but also environmentally as low fuel consumption leads to less greenhouse gas emissions. The lower TSFC values obtained when running LH₂ as opposed to Jet-A give a clear indication that LH₂ is a desirable fuel type both financially and environmentally. Both NPSS and MATLAB simulations achieve the same decreasing trend in TSFC value with an increase in *BPR*. However, the extra capability of NPSS to size a rubber engine and to perform detailed thermodynamics calculations using performance maps gave it an extra edge. This was shown in the steep decrease in the TSFC value compared to the shallower decrease obtained using MATLAB code.

<u>Chapter 5: Performance Study of N+3</u> <u>Turbofan Engine Model with Several Types</u> <u>of Fuels Using NPSS</u>

5.1 Introduction

If we keep the *FPR* constant in Eq. 10 introduced in chapter 3, the exit Mach number also becomes constant leading to a constant exit jet velocity. Thus, the propulsive efficiency depends on only one factor that is the free stream velocity V_o . At constant *FPR*, the propulsive efficiency increases with increasing V_o . However, increasing V_o indefinitely is counterproductive since it would decrease the net thrust generated by the engine (see Eq. (8)). The Thrust Specific Fuel Consumption (TSFC) is better suited to study the performance of a turbofan engine in such cases since it incorporates the amount of fuel used for thrust generation. The equation for calculating TSFC is given in Eq. (11):

$$TSFC = \frac{\dot{m}_{fuel}}{T_{net}} \tag{11}$$

where \dot{m}_{fuel} [lb/hr] is the fuel mass flow rate entering the combustor and T_{net} [lbf] is the net thrust generated by the N+3 technology level turbofan engine.

The amount of fuel needed to generate some level of thrust differs based on the type of fuel used. Different fuels have different heating values which are a measure of the amount of energy that can be extracted during combustion. The Higher Heating Value (HHV) indicates the upper limit of the thermal energy produced during combustion while the Lower Heating Value (LHV) indicates the thermal energy produced minus the latent heat of vaporization of water since it assumes the water produced through combustion is in the vapor form [1]. The useful energy content of fuels is therefore best estimated through LHV. The higher the LHV value, higher is the thermal energy that can be extracted from the fuel.

The aim of this chapter is to study the performance of the N+3 turbofan engine model by altering the *BPR* while keeping the core flow and the *FPR* constant. We also explore alternative fuel sources to conventional Jet-A such as liquid hydrogen (LH₂), liquid natural gas (LNG), and ammonia (NH₃). Their advantages and disadvantages to the performance of the engine and the environment are quantified in this and the subsequent chapter.

5.2 Method

Here again, NPSS is employed to calculate the performance of NASA N+3 geared turbofan engine using different fuels. In keeping with the motivation of this section, the engine was modeled to have constant mass flow through the core and any change in *BPR* is obtained by altering the bypass bleed without changing the core. The solver setup was constructed using dependent and independent variables. The NPSS model utilizes the predefined dependent variables to calculate for the independent variables which are used to analyze the performance of the engine. Table 4 gives a list of the independent and dependent variables used in the solver setup.

 Table 4: Dependent and independent variables used for NPSS solver setup

NPSS Solver Variables					
Independent Variables	Dependent Variables				
Fuel Flow, W _{fuel}	Desired Gross Thrust, F _{gross}				
Fan Pressure Ratio, FPR	Desired Burner Temperature, T_{04}				

Desired Overall Pressure Ratio, OFR	Bypass Ratio, BPR	Desired Overall Pressure Ratio, OPR
-------------------------------------	-------------------	-------------------------------------

Initial estimations of important design parameters are made by scaling the bypass ratio *BPR* with preliminary calculations while keeping the core flow and *FPR* fixed. The initial estimates (see Appendix B) are used to obtain a desired *BPR* value needed to reach the specified thrust level. The variables that change with *BPR* are included as an input file in NPSS (see Appendix C). Fine tuning of the gross thrust from the initial estimates is necessary to reach at the exact *BPR* level when running the simulation. The NPSS model is simulated with the Tt4, FPR, and OPR set to 3150.0°F, 1.3, and 55, respectively. A total of thirteen simulations with *BPR* values ranging from 1-12 and 20 are conducted and the TSFC of the engine is recorded at each *BPR* value. Once the engine model is validated against the MATLAB code [2] for Jet-A fuel, the same solver setup is employed to study the engine performance using liquid hydrogen (LH₂), liquid natural gas (LNG), and Ammonia (NH₃) as alternative fuels. The results from these simulations can be used to quantify the effect of the fuels' energy content on the TSFC of the gas turbine engine.

5.3 Results

Figure 7 shows the change in TSFC with *BPR* based on results obtained from both MATLAB and NPSS codes. As can be seen from this figure, the results from the two simulations agree within $\pm 8\%$. Both simulations show a similar decreasing trend for TSFC as *BPR* increases consistent with the well-known relation between the two quantities. However, the TSFC obtained from the NPSS is below that obtained from the MATLAB at lower *BPR* values; it becomes approximately the same around *BPR* = 6 and becomes higher thereafter. NPSS employs an advanced thermochemical calculation model together with detailed engine map data and

turbomachinery configurations and provides more accurate results compared to the simplified calculation model used in MATLAB.

Figure 7: TSFC vs BPR plot comparing the results obtained from MATLAB and NPSS using the fixed core method.

The above result in Fig. 7 demonstrates that the new NPSS solver setup can replicate the fixed core method used in the MATLAB simulation of [2] with good accuracy. The validated NPSS is then used to investigate the performance of alternative fuels (LH₂, LNG, and NH₃) and the results are compared to those of conventional Jet-A fuel. Figure 8 shows a trend of decreasing TSFC with increasing *BPR* for all fuel types. As can be seen from this figure, LH₂ gives the lowest TSFC value while NH₃ gives the highest; Jet-A fuel results are somewhere in the middle with LNG sitting right below it. This trend is consistent with our expectation based on

the heating values of the fuels. LH₂ has the highest LHV (51,621 BTU/lbm) and hence can achieve the required thrust level by burning lower amount of fuel compared to Jet-A which has a LHV of 18550 BTU/lbm. NH₃ has the lowest LHV (7987 BTU/lbm) and would require much more fuel to get to the same thrust level compared to both LH₂ and Jet-A. Compared to the TSFC value using Jet-A as a fuel , using LH₂ decreases TSFC by 62.5% while using NH₃ increases TSFC by 130%.

Figure 8: TSFC vs BPR plot comparing the performance of three types of fuels in NPSS: conventional Jet-A, Ammonia (NH3), and Liquid Hydrogen (LH2).

5.4 Conclusion

The new NPSS solver setup for the fixed core method was validated against results obtained from MATLAB. The additional capability of NPSS in performing detailed thermodynamics calculations using performance maps gives it an extra edge in sizing and studying an engine model. It is concluded that NPSS can be employed with confidence as a preferred engine performance study tool for research, development, and design of new propulsion systems.

From the study of *BPR* sensitivity on TSFC, it was shown that there is a direct relationship between TSFC and LHV of a fuel. The higher the LHV value of a fuel, the lower is TSFC value. This implies that less fuel is required (by mass) if for example conventional Jet-A fuel is replaced by LH₂. The volume needed to store LH₂, however would be much higher due to its low density. In addition, having LH₂ on board would require a lot more energy since it needs to be kept in a cryogenic tank due to its extremely low boiling temperature [3]. Due to its high volatility, care must be taken during handling. Nonetheless, the environmental benefits of using LH₂, with zero carbon and low NOx emissions, make it a great candidate as an alternative fuel source for sustainable and environmentally friendly aviation. With future advancements in technology and research findings, improved LH₂ delivery and storage infrastructures can be developed to use it as a main source of fuel in aviation. Even though the low LHV of NH₃ makes it less desirable for usage as a fuel source by itself, its environmental benefit and abundance make it a worthwhile alternative fuel source to study.

<u>Chapter 6: Emission studies of N+3 and N+4</u> <u>Technology Level Propulsion Systems with</u> <u>Alternative Fuels</u>

6.1 Introduction

This section outlines the development of a method for estimating emissions within the NPSS framework by utilizing the performance parameters of the N+3 and N+4 geared turbofan engine models published by NASA [1, 2]. Validation of this method is demonstrated by comparing the emissions indexes of Jet-A and LH₂ fuels with published data. Furthermore, the NPSS model is utilized to analyze the emissions and performance of LNG, NH₃ cracking and thermal decomposition of Ammonia-Borane (AB). A detailed description of the emissions calculation and performance comparison between Jet-A and other fuels (LNG, LH₂, NH₃, and AB) is discussed. However, it should be noted that these results are intended to demonstrate trends when comparing alternative fuels and require additional experimental data to conduct a more accurate analyses.

6.2 Methods

NPSS allows for importing emissions indexes into the software's emissions element as a post-processing function. However, accurately predicting the products of combustion for nonmetals is challenging due to their dependence on temperature, pressure, fuel-to-air ratio, ignition timing, and thermal dilution, among others. Therefore, it is crucial to have experimental data with conditions that match the modeled scenario to generate accurate indices for use in NPSS models. Although NPSS can be connected to high fidelity computational fluid dynamics tools, it does not perform specific gas dynamics modeling. To enhance NPSS's capability in providing accurate data for engine performance, an emissions estimation function is developed and validated against published emissions indices. Tables 5 and 6 display the emissions indices obtained from prior investigations on Jet-A and LH₂ combustion in a turbofan engine utilizing NPSS [3]. These indices serve as validation benchmarks until a more extensive experimental data becomes accessible. Assuming the power setting at cruise to be 90% for N+3 and 80% for N+4, the emissions indices of both engines can be determined through linear interpolation.

Table 5: Emissions Indexes for Jo	et-A	١.
-----------------------------------	------	----

Emission Indexes

Approach	30	7.0452	0	0	0	8.94	
Idle	7	3.5872	0	0	0	8.94	

The stoichiometric combustion reactions in chapter 2 are inadequate to accurately estimate emissions for lean mixtures. This is because combustion reactions involve a series of single-step reactions with short-lived species and high reaction rates that cannot be represented by a simple balanced stoichiometric chemical equation [4]. Therefore, this study considers the dominant reaction equations based on the operating environmental conditions. The potential

reactions that may occur during LH_2 and NH_3 combustion are presented in Tables 7 and 8, respectively.

LH ₂ Combustion in Air Reaction Equations
$H + O_2 \Leftrightarrow O + OH$
$0 + H_2 \Leftrightarrow H + OH$
$OH + H_2 \Leftrightarrow H + H_2O$
$0 + H_2 0 \Leftrightarrow 0H + 0H$
$H_2 + M \Leftrightarrow H + H + M$
$H_2 + Ar$
$0 + 0 + M \Leftrightarrow H_2 0 + Ar$
$0 + 0 + Ar \Leftrightarrow H_2 0 + Ar$
$0 + H_2 \Leftrightarrow 0H + H$
$0 + 0H + M \Leftrightarrow H_2 0 + M$
$H + OH + Ar \Leftrightarrow H_2O + Ar$
$H + O_2 + M \Leftrightarrow HO_2 + M$
$H + O_2 + Ar \Leftrightarrow HO_2 + Ar$
$H + O_2 \Leftrightarrow HO_2$
$HO_2 + HO_2 \Leftrightarrow H_2O_2 + O_2$
$HO_2 + H \Leftrightarrow H_2 + O_2$
$HO_2 + 0 \Leftrightarrow O_2$
$HO_2 + OH \Leftrightarrow H_2O + O_2$
$HO_2 + HO_2 \Leftrightarrow H_2O_2 + O_2$
$H_2O_2 + M \Leftrightarrow OH + OH + M$
$H_2O_2 + Ar \Leftrightarrow OH + OH + Ar$
$H_2O_2 \Leftrightarrow OH + OH$
$H_2O_2 + H \Leftrightarrow H_2O + OH$
$H_2O_2 + H \Leftrightarrow H_2 + HO_2$
$H_2O_2 + 0 \Leftrightarrow OH + HO_2$

Table 7: Elementary reaction steps for combustion of Liquid Hydrogen (LH₂) [5].

$H_2O_2 + OH \Leftrightarrow H_2O + HO_2$

NH ₃ Combustion in Air Reaction Equations
$NH_3 + OH \Leftrightarrow H_2O + NH_2$
$NH_2 + NO \Leftrightarrow H_2O + N_2$
$NH_2 + OH \Leftrightarrow H_2O + NH$
$NNH + O_2 \Leftrightarrow HO_2 + N_2$
$H + O_2 \Leftrightarrow O + OH$
$H + NO + M \Leftrightarrow HNO + M$
$20H \Leftrightarrow H_2 0 + 0$

Table 8: Elementary reaction steps for combustion of Ammonia (NH₃) [4].

The Chemical Equilibrium Applications (CEA) thermo-package was selected to conduct the thermodynamic analysis. By using results from the LH₂ combustion, estimations for hydrogen carrier options like catalytic NH₃ cracking and the thermal decomposition of AB can be easily calculated. Under NPSS's CEA thermo-package, the Gibbs free energy is calculated from a balanced combustion reaction and information about the temperature, pressure, and transferred energy is passed on to the next cycle [6]. The Gibbs free energy equation shown in Eq. 12 gives the energy produced with each reaction step. The built-in CEA thermo-package in NPSS calculates the energy extracted from a combustion reaction using this equation.

$$\Delta G = \Delta H - T \Delta S \tag{12}$$

Here, ΔG [kJ] represents the change in Gibbs free energy, ΔH [kJ] is the enthalpy extracted from combustion of the fuel, ΔS [kJ/K] is the change in entropy of the system, and T [K] is the absolute temperature.

Preliminary research conducted in chapter 5 with Jet-A, LH₂, LNG, and NH₃ indicated varying performance characteristics. Moreover, previous published studies have demonstrated that having higher LHV fuels can assist in expanding the compressor surge margin [7]. Thus, accurate performance evaluation has great importance in determining the right fuel type for a specific flight condition. To accurately represent the progression of the combustion, a detailed analysis on the rate of combustion reaction is needed. The addition of reaction rate in the simulation would help to predict emissions with better accuracy. However, this can only be achieved with detailed combustion modeling for which NPSS is not well suited. NPSS works most efficiently with tabulated emissions indexes such as Table 5 and 6. For NH₃ cracking and thermal decomposition of AB, it is assumed that no Nitrogen or Boron will enter the combustion chamber and thus, their emissions are estimated to be similar to liquid hydrogen emissions.

6.3 Results

Tables 9-11 show the performance and emissions of N+3 technology level engine when operated using alternative fuels as compared to Jet-A. While Jet-A, LH₂, and NH₃ are run using the data in the CEA thermo-package, NH₃ cracking and the thermal decomposition of AB are run as the NH₃ and LH₂ fuels, respectively with updated LHVs. LNG is run using CEA thermo-package by assuming that it is fully composed of CH₄ but with an updated LHV that corresponds to LNG. Although not accurate, this assumption is valid since LNG is mainly composed of CH₄ (usually 85-95%) [8]. For catalytic cracking of NH₃, the assumption is 3 mole of H₂ is produced per 2 mole of NH₃ [9]. The byproducts of NH₃ cracking, mainly Nitrogen and its derivatives, are assumed to be expelled into the ambient air through the nozzle. For thermal decomposition of AB, 2 moles of H₂ are produced per 1 mole of AB. Since the combustion of AB produces

crystalline products at the operating burner temperature (T4), the thermal decomposition of AB must happen in a separate unit before fuel injection.

Table 9: Performance and emissions comparison using Jet-A, LH₂, and NH₃ for N+ 3 engine model

The simulation in NPSS does not account for the extra energy needed to thermally decompose AB and thus the specific fuel consumption (SFC) value would be higher than what is given in Table 10. Moreover, only about 13% by mass of AB is turned into hydrogen and thus, the remaining 87% of AB must be stored or sustainably jettisoned.

Table 11: Performance and emissions comparison using Jet-A and LNG for N+3 engine model

Tables 12-14 present the NPSS simulation results for the N+4 technology level engine model. As discussed in chapter 3, the N+4 engine has a smaller fan diameter, lower thrust, and lower bypass ratio as compared to the N+3 engine (see Table 3). Thus, larger SFC values are recorded for N+4 engines. Apart from this, no major difference was observed on the performance of alternative fuels between the N+3 and N+4 engine models. One can see the difference in emissions is merely due to the difference in the thrust level of the two engines and hence the fuel burn rate.

6.4 Conclusion

Here, NPSS was employed to study performance and emissions of N+3 and N+4 engines running on Jet-A, LNG, LH₂, NH₃, and Ammonia – Borane (AB). General cruise cycle performance and emissions data are presented to aid in further research efforts for aircraft and propulsion system designs that take emissions into account. The study showed that LH₂ is by far the cleanest fuel source with no carbon emission and minimal NOx emissions. The emissions from the hydrogen carriers (NH₃ cracking and thermal decomposition of AB) are assumed to be the same as LH₂ emissions, considering that only H₂ is used to generate the necessary thrust. Emissions from the unused byproducts of the hydrogen carriers would either add a weight penalty if kept aboard the aircraft or would contribute to pollution if they are jettisoned to the environment. Since the applicability of liquid hydrogen is limited by the difficulty in transportation and storage, the best alternative fuel source that can be used currently is LNG. The already existing infrastructure supports the transportation of LNG and only minimal modification of propulsion systems would make it possible to use LNG. The main drawback of LNG is the high ignition temperature needed to get the combustion started.

Lastly, it should be noted that although this study utilizes tabulated indexes to estimate emissions, it is not an accurate representation of the actual emissions that involve complex multiple single-step combustion reactions. For future studies, a more accurate emissions calculation that uses burner air flow entry conditions and fuel to air ratio values should be used to estimate the emissions directly from the stoichiometric combustion reaction.

Chapter 7: Summary

This thesis explores future propulsion systems for commercial aircrafts that are currently under development namely the N+3 and N+4 technology level engines. These engines are suitable as propulsion system for an advanced single-aisle aircrafts. Their performance and associated emissions are evaluated. In addition, possible alternative fuel sources are explored with the goal of minimizing emissions while supplying the necessary thrust. The main tool used for performance and emissions evaluation was NPSS.

The validation of the NPSS code was done by comparing its results with results obtained from purely equation based MATLAB code. The usage of compressor maps and detailed thermodynamic tables in NPSS, as opposed to the user supplied limited inputs in MATLAB, brought about slight differences in the results between the two. However, the overall trend and accuracy of the NPSS code was effectively validated.

The results from bypass ratio (*BPR*) sensitivity study showed that there is a significant improvement in thrust specific fuel consumption (TSFC) with increasing *BPR*, giving a step reduction in TSFC at low *BPR* levels which ultimately stabilizes to a smaller reduction of TSFC at higher *BPR* levels. Since increasing the *BPR* ultimately increase the engine size introducing the undesirable consequence of increasing drag, it is crucial to find the optimal *BPR* level for the engine operation. The *BPR* sensitivity study presented in this thesis can be used as a starting point in sizing an engine during design process.

The performance and emissions study of the N+3 and N+4 engines showed that using liquid hydrogen (LH₂) instead of Jet-A gives the lowers fuel consumption rate showing a reduction of 64%. Liquefied natural gas (LNG) follows liquid hydrogen with a 11% fuel

consumption reduction while using ammonia (NH₃) and ammonia-borane (AB) increases the fuel consumption rate by more than 100%. The rate of fuel consumption directly dictates the amount of emissions, thus fuels that lower SFC are the right choice to reduce emissions. Looking at the emissions associated with each fuel, LH₂ is by far the cleanest energy source with no associated carbon emissions and a 72% reduction in NOx emissions as compared to Jet-A. LNG reduces CO₂ and NOx emissions by about 30% and 80% respectively. Although there is no carbon emission associated with NH₃ and AB, they have much higher NOx emissions compared to Jet-A. Although the emissions study presented in this thesis uses indexes, having robust models that can accurately predict emissions associated with alternative fuels are essential for the acceleration of technology development and implementation. In the absence of experimental data, the results presented in this work can be used as a reference for future attempts to enhance the accuracy of emissions estimation model.

Appendix C: Example NPSS Input File

Example input file used in NPSS are given here. The input file consists of the changing variables from the initial estimate Table. Shown here is .inp file for BPR 10. Notice the commented out $(//F_{gross})$ value is the one obtained from the initial estimate (see Table above). The actual gross thrust value that was able to give us the desired BPR level of 10 was 12030.42 lbf and it was achieved through fine tuning.
